AMERICAN JOURNAL OF AGRICULTURAL ECONOMICS

EDITOR / VARDEN FULLER, Universit[illegible]nia, Berkeley

ASSOCIATE EDITOR / HAROLD O. CAR[illegible] California, Davis

BOOK REVIEW EDITOR / ALLEN B. PAUL, University [illegible]

EDITORIAL ASSISTANT / MIRIAM REVZAN, University of California, Berkeley

EDITORIAL COUNCIL

RICHARD O. BEEN, Safeway Stores, Incorporated
JOHN S. BOTTUM, Cooperative Extension Service, Ohio
W. KEITH BRYANT, University of Minnesota
WALTER R. BUTCHER, Washington State University
WILFRED CANDLER, Purdue University
PETER DORNER, University of Wisconsin
WALTER P. FALCON, Harvard University
DONALD E. FARRIS, Texas A&M University
ROBERT S. FIRCH, Stanford University
WAYNE A. FULLER, Iowa State University
ALLEN V. KNEESE, The University of New Mexico
W. NEIL SCHALLER, Economic Research Service, USDA
RONALD A. SCHRIMPER, North Carolina State University
JAMES D. SHAFFER, Michigan State University
ANTHONY M. TANG, Vanderbilt University
GERALD I. TRANT, Rockefeller Foundation, Colombia

EDITORIAL COMMUNICATIONS

Editorial communications, including manuscripts submitted for publication or inquiries concerning the JOURNAL, should be addressed to Varden Fuller, Department of Agricultural Economics, University of California, Berkeley, California 94720. (See inside back cover for Guide for Submitting Manuscripts.)

Communications concerning books for review and books submitted for announcement in the JOURNAL should be addressed to Allen B. Paul, Department of Agricultural Economics, University of Hawaii, Honolulu, Hawaii 96822.

SUBSCRIPTIONS

- Members of the American Agricultural Economics Association receive the JOURNAL as part of their membership.

Yearly subscriptions, $10. Price this issue $2.00.

- Subscriptions, orders for individual copes of the JOURNAL and changes of address of subscribers should beaddressed to C. Del Mar Kearl, Department of Agriculural Economics, Cornell University, Ithaca, New York 14850.

- The AMERICAN JOURNAL OF AGRICULTURAL ECONOMICS is issued five times a year, in February, May, August, November, and December. Prior to 1968, this JOURNAL was the JOURNAL OF FARM ECONOMICS.
- Published by the American Agricultural Economics Association.
- Printed by the George Banta Company, Inc., Menasha, Wisconsin, U.S.A.
- Second-class postage paid at Menasha, Wisconsin.

ARTICLES

Market Power and Its Sources in the Food Industry . . *G. E. Brandow* 1
An Analysis of Cooperative Bargaining in the Processing Tomato Industry . . . . *E. M. Babb, S. A. Belden, and C. R. Saathoff* 13
Cash-Futures Price Relationships for Live Beef Cattle . . *R. L. Ehrich* 26
The Allocation of Research, Teaching, and Extension Personnel in U. S. Colleges of Agriculture . . . . *Willis L. Peterson* 41
Production Economics, Farm Management, and Extension . . . . *Donald B. Williams* 57
An Aggregate Model of Agriculture–Empirical Estimates and Some Policy Implications . . . . *Alvin C. Egbert* 71
A Policy for Public Investments in Natural Resources . . . . *Melvin L. Cotner* 87
An Analysis of the 1964 Wheat Option . . . . *Max Moszer* 100
Econometric Study of Monthly Consumption Expenditures in Rural Uttar Pradesh . . . . *Suresh D. Tendulkar* 119
A Comparison of the Determinants of Wool Production in the Six Leading Producing Countries: 1949–1965 . . *William H. Witherell* 138
Estimation of Performance Functions for Budgeting and Simulation Studies . . . . *Wilfred Candler and Wayne Cartwright* 159
Reliability of Supply Equations Derived from Production Functions . . . . *Larry J. Wipf and D. Lee Bawden* 170

COMMUNICATIONS

Large Farms and Above Parity Returns: Inseparable or Just Good Friends? . . . . *Richard D. Duvick and Joseph N. Uhl* 179
A Lawyer Looks at Water Resource Economists . . . . *Donald R. Levi* 182
Econometricians and the Data Gap:
  Comment . . . . *Ernest W. Grove* 184
  Reply . . . . *John T. Scott, Jr.. and Earl O. Heady* 188

Converting Price Series of Internationally Traded Commodities to a Common Currency Prior to Estimating National Supply and Demand Equations . . . . *Harold F. Bjarnason, Michael J. McGarry, and Andrew Schmitz* 189
Effects of Nonprice Variables upon Participation in Water-Oriented Outdoor Recreation:
  Comment . . . . *Joe B. Stevens* 192
  Reply . . . . *Durward Breuer and Glenn A. Gillespie* 194
On Defining Uneconomic Regions of the Production Function . . . . *J. A. Seagraves and E. C. Pasour, Jr.* 195
On Testing Competing Hypotheses: Economic Rationality versus Traditional Behavior—A Further Development . . . . *Pan A. Yotopoulos and John Wise* 203
  Reply . . . . *Paul R. Johnson* 208
  Rejoinder . . . . *Pan A. Yotopoulos and John Wise* 209
Training Foreign Graduate Students in Agricultural Economics:
  Comment . . . . *Heraclio A. Lombardo* 210

Market Power and Its Sources in the Food Industry[*]

G. E. BRANDOW

Market power is defined in terms of a firm's ability to affect directly other participants in the market or such market variables as prices and promotion practices. The article distinguishes between short-run and long-run power and between offensive and defensive power. More than a dozen sources of power are identified in the food industry. Some of the things commonly regarded as manifestations of market power are unreliable indicators of it. In particular, higher-than-average profits and market power do not necessarily go together.

MARKET power is one of the most elusive terms in economics. Many economists avoid its use, apparently regarding it as lacking in precision or, in the extreme case, lacking any real meaning. Some economists use it interchangeably with "monopoly," "market control," etc., without defining any of the terms. If a single meaning can be extracted from recent literature, it is that market power means an element of monopoly in the sense that the firm possessing it is less constrained in its economic behavior than is a firm operating under pure or perfect competition.[1]

Kaysen and Turner explicitly state such a definition: "Where firms can persistently behave over substantial periods of time in a manner which differs from the behavior that the competitive market would impose on competitive firms facing similar cost and demand conditions, they can be identified as possessing market power" [6, p. 8].[2] Mason implies a similar meaning in his frequent parenthetical definitions, for example, ". . . the preservation of competition, meaning the exclusion of positions of market power . . ." and "Market power, that is to say, some protection from a competitive forcing of prices toward short-run marginal cost . . ." [7, pp. 92, 93].

The Kaysen and Turner definition has the disadvantages of defining market power by indirection, of using a logical construct rather than a real-world situation as its reference situation, and of dealing only with

[1] This article does not deal directly with bargaining power, a topic of much current interest among farmers. A firm or group obviously needs some market power to bargain meaningfully, but market power may not be exercised through a bargaining process. K. R. Farrell makes a similar distinction [3].

[2] Kaysen and Turner refer to the perfect competition model. Pure competition as used in the present paper differs from perfect competition in not requiring perfect knowledge and factor mobility

---

G. E. BRANDOW *is professor of agricultural economics, The Pennsylvania State University.*

long-run power. It seems better to define market power directly, along the following lines: A firm may be said to possess market power if a price, production, marketing, or purchasing decision it might practically make can directly and materially affect the incomes of other firms or persons or can appreciably change the average price, total quantity, or marketing or purchasing practices in a market in which it participates. A firm with market power in selling can change its rivals' sales volumes if it substantially changes its prices or promotion activities, and hence can change its rivals' incomes, unless the rivals adopt counter measures; and in that case, market-wide prices or promotion practices will be altered, as a minimum. Analogous statements could be made about a firm with market power in purchasing materials or in hiring labor. If the firm has no market power in any respect, its customers, suppliers, and employees have enough alternatives so that they can avoid the unilateral action of the firm without significant loss to themselves.[3] In short, a firm with market power can make waves; a firm without market power cannot.

It is well-known, but worth repeating, that market power has many gradations ranging from none at all when the firm operates under strictly pure competition to great power when the firm has an unregulated monopoly in the sale of an important product with an inelastic demand (or a monopsony in the purchase of materials or the hiring of unorganized labor with inelastic supplies). A firm may have little or no power in one market but considerable power in another—for example, a canning company may have substantial power in the purchase of a certain vegetable in one growing area, very little power in selling the processed product in a private-label market, and only slight power in employing labor.[4]

Though the distinction is necessarily imprecise, a difference between short-run market power and long-run market power is important. Short-run power exists if the firm can materially affect the market or other participants in it over some short period of time—say, up to two or three years. Long-run power endures for more extended periods, as for a decade or more. A large fluid milk processor might be able to raise the into-store price in a particular metropolitan market for a year or two but then lose his power as smaller rivals expanded their plant capacity and undersold him, as new processors entered the market, or as large retailers vertically integrated into processing. If, however, the large processor could induce rivals to follow his price lead and new processors of all types were kept out of the market, perhaps by legal barriers, the firm would have long-run market power. The time ordinarily necessary for rivals to expand, for new firms to enter the market, and for other undermining developments to occur distinguishes the short run from the long run.

---

[3] Legal restriction may also modify or to an extent re-direct market power available to a firm.

[4] Quantitative measures of the degree of market power are not easy to devise. Power differs for different purposes. As argued later, profit rates indicate market power only in certain instances. Market shares and concentration ratios indicate two important sources of market power but do not measure power itself.

A firm having substantial market power is likely to be circumspect in its use *if* the power appears to be short run only. Then, many of the short-term advantages it might gain would be more than offset by subsequent losses. Such a firm is in the position of being able to retain its short-run power over a period of years only it it uses the power with restraint. It has power to prevent short-run instability in its markets and to do well for itself in some temporary situations, but it should not adopt methods that would eventually bring new or expanded rivals into the market. A firm may, of course, misjudge its power or in fact have long-run power.[5]

The distinction between short-term and long-term power is instructive about the important but notoriously fuzzy concept of workable competition. Short-run power may contribute to good performance by stabilizing markets and by permitting innovations to be introduced under favorable circumstances, while long-run power that might reduce efficiency or progressiveness may be much less assured to firms and hence little abused. Thus, obvious departures from pure competition may fail to impair performance as predicted by standard theory. The short-run, long-run distinction also highlights the importance of conditions of entry into an industry as an influence on market power and performance there.

Another useful distinction is that between offensive and defensive market power. A firm may have substantial short-run market power and have large financial resources upon which to draw, yet the firm may judge that its long-run interests are best served by operating in a routine fashion. It is not likely to take the offensive against rivals, buyers, or suppliers in an effort to increase its profits or market share. But if another firm takes offensive action, the first firm will be able to adopt potent counter-strategies and to survive for a long time. The firm has more defensive than offensive market power.

Sources of Market Power

Review of the food industry suggests that market power can arise from several sources.[6] Most of the following discussion is in terms of selling but also applies to purchasing and to employment of labor. The principal sources of market power, not necessarily in order of importance, are:

---

[5] Fellner distinguishes between the short run and the long run in discussing profit maximization. Although to him "the profit incentive is not typically a short-run incentive," he points out, among other things, that "the pricing problem is in a sense a short-run problem" and that "high profits may induce outsiders to take up competition" [4, pp. 158, 161].

[6] Observations are based largely on the work of the National Commission on Food Marketing, whose results were published in a final report [9] and in ten technical studies.

1. **Large size in relation to the relevant market.** The larger the firm's market share, the more its own prices, production, promotion, etc. contribute to market-wide aggregates and the greater will be the firm's ability to modify the market situations faced by others. Rivals are more compelled to follow a price reduction or adopt a promotional device initiated by a firm with a large market share, and they can more confidently follow such a firm's price increase in the expectation that it will hold. Of all sources of market power, this one—market share—is most often emphasized in economics literature and requires no elaboration here.

2. **Large financial resources.** Firms of equal size and market shares may differ in the extent to which they are financed by equity capital or have ready access to additional funds. The firm with the larger financial resources can better survive competitive battles or its own mistakes and can accept more risk in launching new ventures. Firms weak in this respect will not be inclined to oppose the strong firm and have an unequal chance of success if they do. An important means by which some firms have increased their strength from this source in recent years has been by becoming a subsidiary of a large and well-financed conglomerate. Financial resources are highly associated with market share, diversification, and vertical integration.

3. **Diversification over products.** In simple diversification, the firm produces several related products rather than one or only a few; in the more complex case, the firm is a conglomerate operating in several industries not closely related to each other. Diversification reduces the firm's dependence on any one product and increases its options in pursuing offensive or defensive tactics in a single market. This is especially true for the conglomerate, which may be able to engage in market share struggles in an industry without affecting the sources of most of its income. The assumption is made here, of course, that the firm does not gain diversification at the expense of efficiency.[7] Where this is true, rivals in any market are likely to recognize the greater strength of the diversified firm. The firm may also be able to avail itself of market-power benefits of the full-line seller over a limited-line firm, and tactics such as reciprocal dealing may give it special advantages.

4. **Geographic extension over local markets.** A firm operating in a number of independent local markets, e.g., a large food chain or bread baker, is much like a conglomerate in the sense that tactics it adopts offensively or defensively in one market need not seriously threaten its income or

---

[7] Sometimes a highly specialized producer is more efficient in serving a part of the market than are conventional firms and thus can encroach on their business. This has been one of the reasons for the growth of jug milk operations, for example.

financial position. Comments about conglomerates in this regard apply to firms operating in several independent local or regional markets.

5. **Vertical integration.** The vertically integrated firm is diversified over successive stages of production and distribution rather than over products or local markets (though it may be diversified in those ways as well). The fortunes of the firm, therefore, are not tied exclusively to its performance of a single function, and it can call upon resources from other operations in power struggles in any market in which it nominally participates. For example, a flour milling firm that is integrated forward into the manufacture of such flour products as cake mixes and snacks is less vulnerable to severe price squeezes in milling than is a specialized miller.

A vertically integrated firm with a large market share at one stage may have opportunities to squeeze unintegrated rivals at other stages or to influence prices directly. Known examples in the food industry are few and are subject to conflicting interpretations.

6. **Membership in an oligopolistic core: concentration.** A large market share usually is one source of a powerful firm's influence. Frequently such a firm finds itself one of a small group of firms that collectively account for a large portion of the total market volume. The inescapable interdependence among the dominant firms in this case is a strong inducement for each to adopt pricing, marketing, and other practices tolerable to, if not preferred by, other group members. One firm's market power then depends on its influence in the group and on the group's influence in the total market. The strongest member of the group—and this may well depend on power sources other than market share—can strongly influence group behavior and thus enhance the firm's own power. A weaker member of the group usually will at least have veto power over group action. Each firm of the oligopoly core both gains something from being a member of the group and gives up some of its independence to the imperatives of group discipline. The existence of concentration in the market is not a simple addition to or subtraction from power gained from other sources by one of the leading firms, and it modifies the context in which any power can be exercised.

The oligopoly group may be strong or weak, depending on its market share, ease of entry by new firms or expansion by small ones, product differentiation, type of buyer, and still other circumstances, several of them discussed here as sources of power for individual firms.

7a. **Product differentiation, including new products.** The firm that succeeds in convincing numerous buyers that its particular product has some unique merit over others has in a sense established a new product over which it has complete monopoly. Ordinarily, however, the monopoly will be weak, for similar products sold by other firms will be close if not perfect substitutes in the minds of buyers. One of the most potent forms of product differentiation is a distinctly new product of genuine usefulness to large numbers of buyers; until other firms succeed in producing the same or similar product, the innovator has a strong monopoly.

Product differentiation in the food industry, however, usually takes the form of brands and "new" products that differ from others, if at all, only in minor respects. Promotion, mainly advertising, is the principal means of establishing strong impressions of unique merit. The resources and skill with which to promote products on a national or at least regional scale often are crucial to successful product differentiation and hence to this source of market power. Economies of size in promotion may be a more important influence on size of firm than is efficiency in physical operations [10, pp. 61–104].

7b. **Access to consumers.** This item is an important elaboration of the foregoing one. The expertness of buyers is crucial to the power to be gained from product differentiation by sellers. An industrial buyer of a material that will lose its identity in a manufactured product ordinarily will bring much technical knowledge to the task and may have considerable testing equipment at his disposal; only genuine and significant product differentiation will interest him. Frequently, moreover, he can express the quality characteristics he wants in technical terms and buy on specification, in which case the seller can claim no product differentiation.

Consumers, in contrast, are not expert buyers of most things they purchase, nor do they have the time or resources to act in expert fashion if they were. They are easily convinced—will even convince themselves—that product differences exist where none in fact do,[8] and they value prestige and change even where these are not related to intrinsic product quality. The comparative expertness of buyers makes a fundamental difference between consumer goods industries and producer goods industries with respect both to sources of market power and to several aspects of performance.

Both food manufacturers and retailers have access to consumers—manufacturers by advertising, couponing, etc., and retailers mainly by operating the stores where consumers shop. Farmers usually have no access to consumers, though some farm products are advertised and retain their identity when they reach consumers. The dairy industry provides an example of shifts in market power due to access to consumers: the decline of home delivery of milk and the shift to private label sales to food retailers probably have been important factors in the apparent decline of the market power of fluid milk dealers.

8. **Structure of buyers, especially their size and number.** Dealing with

---

[8] In a controlled study, consumers were found to develop brand loyalties for products that were identical even though no advertising was used; amusing examples are given of consumers' confidence in their judgment [8].

large firms on the other side of the market tends to reduce a firm's market power. Since obtaining market outlets often is more limiting to firms' growth than are production problems, the volume represented by a single large buyer makes his business especially attractive to sellers capable of handling it. Once such a firm becomes a customer, loss of its business may be serious to the selling firm. Oligopsony among buyers tends to encourage them to present a united front to sellers. The large buyer has the ability to be a highly expert purchaser, to seek out the best deals available anywhere in a large procurement area, to develop his own brands, and often to integrate into the supply industry if the best possible terms are not offered. The rise in the importance of chains and wholesale buying groups has been a leading reason for the growing power of food retailers relatively to suppliers.

9. **Elasticity of demand for the industry's product.** The opportunity for an oligopoly group to influence selling prices can be great when demand for the industry's product is highly inelastic; the opportunity is necessarily small when demand is highly elastic. The same general idea applies to purchasing and to labor markets. The elasticity of demand facing any one of many firms will be greatly different from the elasticity of industry demand, but probably an inelastic industry demand favors the power of a firm with a large market share to influence price. The mutual interest of the firm and its principal rivals in maintaining prices at as high a level as long-term considerations—e.g., entry of new firms—permit will strengthen tendencies toward price leadership-followership behavior. This may be especially pronounced when costs are rising, for then higher prices do not necessarily increase profits and thereby attract new firms or encourage expansion by old ones.

10. **Operating efficiency, marketing effectiveness, and progressiveness.** When oligopolistic firms' market power derived from other sources is about equal, the firm with particularly low costs, outstanding ability to promote its products, or exceptional progressiveness in introducing new operating methods or products is likely to be granted a leadership role by its rivals. Operating efficiency will be especially important when products are not readily differentiated; the low-cost firm will have one of the lowest preferred prices of the oligopoly group and probably will be one of the first to limit price increases in the industry. Where product differentiation is high, the firm that promotes old products or introduces new ones especially effectively is likely to be the industry leader and may be able to obtain prices substantially higher than those at which run-of-the-mine firms can sell. The lesser firms follow the dominant firm by discounting their prices below its prices by rather standard amounts.

11. **Other sources of market power.** Some factors affecting market power may reduce or eliminate power that otherwise would exist. Chronic

excess capacity in a market, which may result from declining demand or from new availability of supplies from other areas, makes at least some firms especially eager to get extra business at almost any price exceeding direct costs. Cutthroat rivalry may develop, making it impossible for any firm to exercise much control over prices or marketing practices. A mild example on the purchasing side is the scramble for Class II milk by manufacturers in fluid milk markets when the supply is well below manufacturing capacity. Abnormally large inventories weaken a firm's position in a selling market, especially if the product is perishable; as the saying is in meat packing, "Sell it or smell it."

Firms may have market power conferred upon them by weakness, usually temporary, of those with whom they trade. For example, retailers are in a strong position if fluid milk dealers with excess capacity are desperate for sales, and processors of a farm product are likely to benefit from sudden increases in supplies. Patents have occasionally been the basis upon which market power originally was built, as in the case of the Kraft-Phenix Cheese Corporation [5, p. 49], but they are not now widely important in the food industry. Collusive, unfair, and deceptive practices are likely to add to market power as long as they go unchecked. Strong-arm tactics and underworld methods are not trivial.

Antitrust and related regulation have had substantial direct and indirect effects on structure and conduct in the food industry and thus on market power of firms.[9] Federal and state marketing orders have strengthened the power of several bargaining associations in fluid milk, fruit, and vegetable markets. Political influence exercised by large food firms, trade associations, and farm groups has supplemented economic power; in the case of large firms, the sources of political and market power have much in common.

Manifestations of Market Power

The definition of market power suggests the means by which it can be detected directly: by observing ways in which the firm having power affects prices, marketing, procurement, or hiring practices or, more commonly, induces reactions among other firms that lead to market-wide changes in such variables. Price leadership in selling or in purchasing is a common example in the food industry. The equivalent of price leadership is often seen in promotional activities. For example when one food chain in a local market adopts stamps or games, other leading retailers frequently adopt similar promotions. Or some retailers may go in another direction, price discounting, which is not followership but is nevertheless a reaction induced by the first firm.

---

[9] Though antitrust regulation has in general tended to dilute market power, the effect has not been entirely one-way. For example, action against horizontal mergers probably has increased conglomerate mergers, and in some instances the Robinson-Patman Act may assist a seller in maintaining prices

Manufacturers may for a time refuse to sell private label products, thereby displaying power on their part, but then cave in when a chain shows its power by undertaking—or by seriously threatening to undertake—its own processing. Exchange arrangements between buyers and sellers, together with the context in which the arrangement is made, may reveal market power. As an example, contracts only one grow-out period long may seem to be equally risky to broiler integrators and to growers, but two facts indicate that the arrangement reflects superior market power by integrators: (1) potential supply expansion is large through entry of new growers and increased production by old ones, and (2) failure to renew a contract ordinarily is more damaging to the grower than to the integrator.

The ways in which market power may be exercised are many and subtle and may not be readily apparent to the outsider. Intimations from businessmen themselves are therefore informative. What rivals do they watch most closely; what customers do they service with greatest alacrity? The pecking order at a trade association meeting largely reflects industry opinion as to who has market power and who does not.

High profits are a common objective of the use of market power, though, as Galbraith and others have persuasively argued, other objectives also are important. Consistently high profits for a firm, however, are not necessarily proof of great market power. An unusually well-managed firm may make distinctly better-than-average profits under pure competition. A giant firm with great market power may no longer be a good performer or may be holding a price umbrella for much smaller but more profitable firms. No one would suppose that the profit rates of A & P and Weis Markets are indicative of the current market power of the two food chains—but he might see a hint for the future.[10]

High average profits for the oligopolistic group in an industry probably reflect market power unless caused by temporary conditions. Four breakfast cereal manufacturers, accounting for 85 percent of shipments, made 19.4 percent on net worth after taxes in 1964; food manufacturers as a whole earned an average of 9.8 percent that year [9, p. 67]. On the other hand, a group of large firms may have significant market power though not unusually high profits. The market power of food retailers has risen substantially in the past two decades or so and has been used to bring about numerous changes in market channels, suppliers' services, position of manufacturers' brands, and methods of vertical coordination from farm to retail store. Small, independent retailers could not have done these things. But power to influence the supply system has been available to some degree to most substantial retailers and group wholesalers. Rivalry among retailers has been keen enough to cause most of the potential gains from market power in relation to suppliers to be competed away[11]—partly in the form of higher promotion costs.

---

[10] In the year most closely corresponding to calendar 1966, A & P, with 4,693 stores and sales of $5,475 million, earned 9.2 percent on net worth after taxes; Weis Markets, a Pennsylvania chain, had 55 stores, sales of $126 million, and profits of 21.7 percent. A & P was not the least profitable of the large chains, nor was Weis Markets the most profitable of the smaller chains [11, p. 22].

Farmers, who commonly sell under pure competition when prices are not fixed by government programs, often regard ability to quote a selling or buying price as evidence of market power. But many sellers or buyers with little market power quote prices. Usually, conventions have developed as to whether buyers or sellers quote prices, and the conventions appear to be based on efficiency and practicability. Retailers have more market power than their suppliers in some markets where sellers conventionally quote prices. A related notion is that if there are price takers there must be price makers, in the sense of setting prices. Both sides of a market may be purely competitive, however. Even where some degree of oligopoly or oligopsony exists at all stages of distribution, average prices for a quarter or half year may not differ materially from those to be expected under pure competition; beef appears to provide a fairly good example.

Concluding Comments

Attention to market power in the food and other industries is only recognition that a degree of oligopoly characterizes most of the American economy. When a market is not purely competitive, firms have joint price, output, and, often, promotion decisions to make in selling (or analogous joint decisions in purchasing supplies or hiring labor). Firms then have options that purely competitive firms do not and commonly will be aware that the decisions made by at least some individual firms will have a direct and immediate impact on all. Such firms have power, and power and rivals' reactions to it will be taken into account in choosing among options.

The resulting behavior, especially in the short run, is different from that in a purely competitive market. Some firm must, of course, initiate a price change when one occurs under pure competition,[12] but which firm makes the first move is likely to be a random matter and to have no effect on subsequent events. Innovations are made under pure competition, but the adoption of a superior method or product by a single firm has no direct effect on any other, and only imitation by many competitors in search of profits gradually affects prices and brings about industry-wide change. Obvious differences in price and output stability, manner of price change, introduction of innovations, and other aspects of behavior result under the two market structures. The psychology of markets is also different; under oligopoly, rivalry is personal, firms have character, power is part of the industry environment; under pure competition, everything focuses impersonally on price, and producers may not even regard each other as rivals.

---

[11] In 1965-66, sixty food chains had after-tax average earnings on net worth of 11.48 percent [1, p. 10]; average earnings of manufacturers of foods and kindred products in 1966 were 11.2 percent [2, p. 293].

[12] When both buying and selling are purely competitive. Changes in prices for farm products often are initiated by buyers who are not purely competitive.

The presence or absence of market power is not an indication of the quality of industry performance, a topic too complex to develop here. Schumpeter, Galbraith, and others are surely more right than wrong when they argue that market power has positive virtues in a dynamic, technologically advanced economy. Moreover, pure competition is not a feasible alternative for most industries, including foods—the costs of sufficiently small production units are too great. The art of getting good performance involves accepting many necessary and often useful forms of power while preventing those that threaten the effectiveness of the competitive—though not purely competitive—system.

Of the numerous sources of market power, a significant market share usually is necessary, and a large market share is sufficient in the short run. A firm with a large share of the market cannot avoid substantial influence on rivals, customers, and suppliers, and on prices or associated market variables, if it makes a significant move in any direction. High product differentiation gives a firm 100 percent of a market that is in some degree insulated from others. Several others sources of market power have in common the capacity to enable the firm to survive while it pursues aggressive tactics of its own or defends itself against its rivals. Large financial resources and diversity over many product lines or geographically limited markets serve this purpose, and vertical integration, superior operating efficiency, and great marketing ability contribute something to it. Market power is not equivalent to the ability to make high profits, though that may be one of its effects, and conventions as to who quotes prices are not reliable indicators of market power.

An Analysis of Cooperative Bargaining in the Processing Tomato Industry*

E. M. BABB, S. A. BELDEN AND C. R. SAATHOFF

This article analyzes factors which affected the bargaining process and outcome of negotiations for the processing tomato industry in Indiana and Ohio during the 1966 growing season. Data obtained from Indiana and Ohio tomato processors, grower representatives, and growers was used to reconstruct the bargaining process to determine what factors were considered in establishing contract objectives, to determine various factors each party thought affected bargaining strength and the outcome of negotiations, and to measure attitudes about bargaining.

Substantial differences were found between the parties' conception of supply and demand response and those estimated statistically. Processors and grower representatives underestimated supply response and consumers' response to higher prices. Significant differences between grower and processor attitudes toward bargaining were identified. Processors were primarily concerned about quality factors and growers with price. This suggests that a "trading off" of concessions would benefit both parties.

THE purpose of this article is to analyze factors which affect the bargaining process and the outcome of negotiations in a specific industry at one point in time: the processing tomato industry in Indiana and Ohio during the 1966 growing season.

Theoretical Framework

Previous studies

Previous studies of bargaining can be classified as those using controlled experiments and those that analyzed specific bargaining situations.[1] Most of the controlled experiments have examined the pattern of bargaining behavior in a simplified situation where one factor affecting outcome was varied in a series of experiments [see, for example, 1, 8, and 9]. Factors that were varied include level of information among rivals, number of rivals, number of bids and offers, level and differences in incentives or pay-offs, psychological traits of bargainers, communication among rivals, and the like. This approach offers the opportunity to observe how the behavior of bargainers corresponds to that hypothesized under controlled conditions. A shortcoming is that the experiment must necessarily be rather simple compared with reality and there may be considerable

interaction among the variables which are treated independently in separate experiments. In addition, the subjects for the experiments have usually been college undergraduates and generalizations based on the behavior of sophomores is risky.

Studies of actual bargaining situations in agriculture have been limited to milk and specialty crops [3, 4, 5, 6] and those outside of agriculture mainly to labor negotiations.

Schneider analyzed the possibilities of bargaining success under different demand and supply elasticities and focused on determining the economic negotiotion limits [6]. Siegel and Fouraker [1, 8], through controlled experiments, analyzed the role of information and other factors as they determined the price negotiated within the limits prescribed by economic forces. This study attempts to build on these earlier works by analyzing economic and non-economic factors that influence the bargaining process and outcome in an actual situation These same factors are hypothesized to be strategic in terms of reaching an agreement. The general hypotheses to be tested were:

1. Historical and organizational factors influence bargaining power and the bargaining process.
2. Growers and their bargaining representatives do not have common contract objectives and homogeneous attitudes with respect to bargaining.
3. Processors do not have uniform contract objectives and attitudes toward bargaining.
4. Buyer and seller objectives and considerations in establishing objectives are different, creating conflicts to be resolved.
5. Grower objectives and attitudes are different according to farm characteristics and organizational affiliation, i.e., not homogeneous.
6. Grower, grower representative, and processor conceptions of economic factors related to supply and demand for tomatoes are not consistent with empirically verified relationships.
7. The nature of supply and demand relationships is such as to create conflicts to be resolved in the bargaining process.

Data

Data was collected from Indiana and Ohio processors and grower representatives in June and July of 1966, after the contracts for the season

---

fecting Cooperative Bargaining in the Processing Tomato Industry," unpublished M.S. thesis, Purdue University, 1968. Helpful comments and suggestions by Paul Farris, Don Paarlberg, and George Ladd are gratefully acknowledged.

[1] In addition, there have been numerous descriptions of bargaining situations for particular commodities, mostly reported in *Proceedings—National Conference of Fruit and Vegetable Bargaining Cooperatives*, FCS, USDA, Washington, D.C., 1957–1968.

had been established. During a personal interview with processors, a questionnaire was administered to generate the basic data for the study. A tape recorder was used to register the reconstruction of bargaining activity. Five complete questionnaires and one partially complete questionnaire were obtained from a population of ten tomato processors who had negotiated a contract for raw tomatoes with the bargaining committee of the grower organization. This contract was written for all members delivering to the processor and usually for any nonmembers. Twenty processors from a population of twenty-six who had not negotiated a contract with the bargaining committee in 1966 but had dealt with growers individually completed a questionnaire. Similar questionnaires and methods were used to obtain data from seven grower bargaining committees with a total representation of 25 members, and a group interviewing technique was used to reconstruct bargaining activity. Three officials of the Indiana Agricultural Marketing Association (I.A.M.A.) and the Ohio Agricultural Marketing Association (O.A.M.A.), affiliates of the American Agricultural Marketing Association, provided data.

A mail questionnaire was sent to all members of the two associations in October 1966. A total of 473 usable questionnaires was returned (66 percent), considered satisfactory in view of the fact that some association members were pickle or sugar-beet growers.

The above data consisted of respondents' estimations of supply and demand factors, factors considered in establishing contract objectives, factors affecting bargaining strength and outcome, and scales to measure attitude toward bargaining and bargaining associations. Secondary data were used to estimate statistically supply and demand relationships.

From a methodological standpoint, two interesting problems arose. The first was the processors' reluctance to discuss their pricing and bargaining philosophy. Only under the assurance of strict confidence would they discuss such sensitive matters at all, and even then they considered certain information to be classified. The second problem was their wariness of the tape recorder. Virtually all would have preferred not to use it, and some would not allow its use. Undoubtedly future studies of bargaining will encounter similar sensitivity problems. Careful planning and advance contact should be made to allay respondents' apprehensions.

Analysis of Bargaining

The process

In both Indiana and Ohio, negotiations are conducted annually with individual processors. However, one of the national packers is selected for initial bargaining in an attempt to set the pattern for the rest of the individual processor negotiations. A local bargaining committee of the marketing association is responsible for negotiating with each processor; it is elected from the total local association membership selling to that processor. All negotiations within a state are conducted under the guidance of the state association.

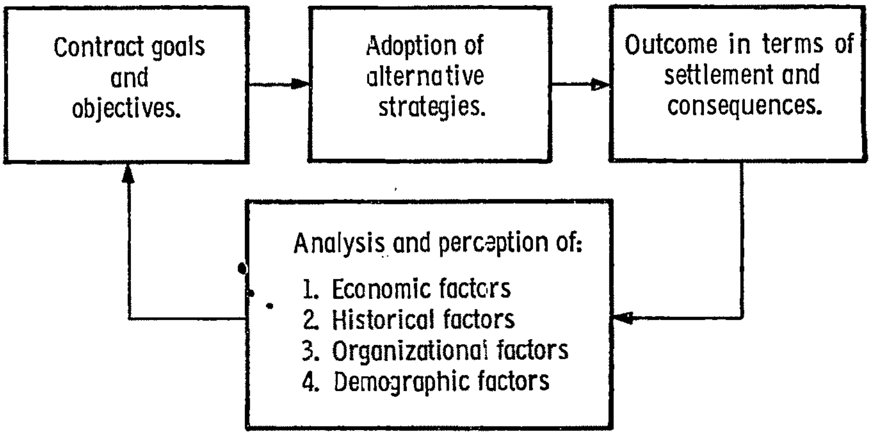
The first step for both processor and grower representatives is to formulate their objectives for the contract; after that, they are ready to bargain. Typically, the bargaining committee makes the initial contact with the processor; then the negotiation follows a pattern consisting of three stages.

Stage one—the processor recognizes the association as the bargaining agent for its member-growers. (The processor is currently under no legal obligation to recognize the association and may at any time refuse to deal with it.)

Stage two—each side announces its contract objectives for the forthcoming growing season, thus signalling the beginning of direct bargaining.

Stage three—attempts are made to resolve differences and negotiate a contract. This stage continues until agreement on a contract or until either side withdraws from the negotiation. During this period either side may attempt to influence the other's position through the use of various strategies.

This bargaining process is illustrated in Figure 1, which suggests that bargaining parties' contract objectives are related to their perception of economic, historical, organizational, and demographic factors which they translate into relative bargaining power. Strategies are dictated by the level of goals and determine an outcome; this may be a stalemate, in which case the process may continue or terminate. Although some perceptions may be incorrect (an apparent case in point is discussed later), they do help to explain the behavior of parties to the negotiation. Identification of misconceptions may be used to reconcile expectations with outcomes; and, as a result, the bargaining process may work more smoothly.



Contract goals and objectives.
Adoption of alternative strategies.
Outcome in terms of settlement and consequences.
Analysis and perception of:
1. Economic factors
2. Historical factors
3. Organizational factors
4. Demographic factors

Figure 1. Model of bargaining process in tomato industry

Contract objectives

In the aggregate, there was significant agreement as to contract terms desired (Table 1) within each of the groups (growers, grower representatives, and processors), as indicated by Kendall's coefficient of concordance. There were differences, for example, between growers in the two states, between growers with different organizational affiliation, and the like, which will be discussed later. It is apparent that growers were interested primarily in price and processors interested in quality, which suggests areas for a "trading off" of concessions.

Table 1. Comparison of growers, grower representatives, and processors in their rankings of contract terms desired

Contract term desired	Pooled rankings[a]	
	Growers	Committeemen
1. Improved grading	2	3
2. Increased acreage	6	6
3. Higher prices	1	1
4. Elimination of hamper restriction	5	4
5. Assistance in production or harvesting	4	5
6. Improved terms of delivery	3	2

Contract term desired	Processor
1. Year-to-year stability in production	3
2. Year-to-year stability in growers	4
3. Low price for raw tomatoes	5
4. High levels of production	2
5. Production of the quality of tomato you desire	1

[a] Value of Kendall's coefficient of concordance for growers' rankings was .464, for committeemen's rankings it was .423, and for processors' rankings it was .888. All coefficients were significant at the five percent probability level.

To determine the importance of various factors influencing the contract objectives of each party, the interviewees were presented with a list of factors hypothesized to affect their objectives. They were asked to indicate whether they had considered each factor, and of those considered, to rank the five most important.

On the basis of the background data from the questionnaire and the taped portion of the interview, an analysis was made of the variation in the processors' attachment of importance to specific factors. The importance of these factors was determined by weighting the percent of processors who considered the factor and the rank weight the factor received. The factors are here arranged in order of decreasing importance.

1. Other raw tomato contracts offered—All processors considered this had an effect on their objectives. The smaller regional canners tended to rank this item among the five most important; the national canners did not.

2. Method of grading raw tomatoes—Differences in processor response were related primarily to whether they used a Federal grading system. The one canner who used his own grading system felt this was an important factor in establishing his contract terms.

3. Alternative sources of supply—The larger national canners felt it would be easier to obtain new growers or develop new areas of production than did the smaller canners. The greater importance attached to this factor by large canners appeared to be related to feasibility.

4. Size of the finished product carryover—Differences in response again appeared related to firm size. The national canners attached more importance to this than did the smaller canners, primarily because they use carryover information as a variable in their pricing decision while the smaller canners tend to follow the price established by the nationals in both finished and raw product markets.

5. Growers' average costs—This factor was more important to the national canners than to the smaller canners. The main organizational and bargaining thrust by the associations has been directed toward the larger canners who are thus made aware of growers' costs as part of the association rationale for their contract demands.

Non-bargaining processors were asked to rank a similar set of specific factors, and the importance of these factors was evaluated in the same fashion. The results were the same as for the bargaining processors, except that this group also considered growers' loyalty to the processor.

Grower representatives also evaluated a set of factors hypothesized to affect their objectives and ranked the following as most important: their strength in a processor's procurement area, other raw tomato contracts being established, growers' average costs, method of grading, processors' alternatives to utilizing growers' tomatoes, growers' alternatives to dealing with the processor, and the processor's tendency to over-contract.

Strategies

During the course of negotiation, either party may attempt to influence the other party's objectives or to alter his conception of his own position, through various strategies. Processors' strategies included: (1) attempting to contract with non-member growers before the contract had been settled with the association, (2) pointing out fallacies in the bargaining committee's rationale for its terms, (3) using other contracts being established to strengthen the rationale for their position or weaken the rationale of the bargaining committee's position, and (4) reminding member growers of the services supplied to them by the processor.

Strategies used by bargaining committees included: (1) attempting to use other contracts being established to strengthen the rationale for their position or to weaken the rationale of the processor position, (2) conditionally approving a contract (i.e., accepting the processor's contract with the condition that he agree to pay the "going price" in the area), (3) attempting to condition the bargaining environment by articles in newspapers and the like, and (4) offering services to the processors.

Outcome

No attempt was made to predict or evaluate the prices, acreages, or other terms of trade negotiated. Higher prices and terms of trade more favorable to growers were negotiated in 1966, although agreement between grower representatives and processors was not reached in all cases. Agreements with major processors were not reached until very late in the season (May), which created difficulty for both growers and processors.

Factors Affecting Objectives and Outcome

Economic

Economic forces place restrictions on the terms of trade that can be negotiated. Higher prices can be negotiated more readily if consumers are not responsive to price increases. Likewise, bargaining for higher prices is more feasible when farmers do not greatly increase production in response to higher prices.

Grower representatives and processors were asked to estimate the degree to which acreage would be added in response to higher raw tomato prices. In general, they felt this response would be quite small.

The supply response for planted acres of tomatoes in Indiana and Ohio was estimated by least-squares single equation regression, using the following data: 1946–65 acreage planted; average seasonal tomato price received by farmers deflated by index of prices paid; six-year moving average of tomato prices deflated; weighted index of alternative crop prices deflated; and a production cost index.[2] Short- and long-run price elasticities of supply of planted acreage for Indiana were 2.18 and 4.49, respectively; and for Ohio, 1.05 and 2.65 (significant at 5 percent level). These supply elasticities imply difficulty in maintaining price and income gains from bargaining, in the absence of supply management. The difference in responsiveness as estimated by grower-representatives compared with the statistical analysis may result in misjudging the need for supply control.

Asked to estimate consumer response to higher tomato product prices, processors felt that consumers were responsive to price differences between brands (low-brand loyalty) but were fairly unresponsive to changes in the level of price. A statistical analysis of demand relationships resulted in a price elasticity of −.76, but the coefficient was not significant. Much of the difficulty in estimating demand relationships was attributed to data problems. Shuffett estimated the price elasticity of demand for tomato products at the retail level to be −.40 [7]. He also pointed out data limitations. If the demand elasticity lies within the range of the above coefficients, processors are probably underestimating consumer responsiveness and grower representatives are not according this factor enough weight in setting contract objectives.

---

[2] Attempts to use two-stage least-squares estimation procedures were handicapped by specification of state supply areas and national market for product, as well as converting acreage and volume data. The procedure used does reflect the situation in which price is fixed prior to each year's planting and acreage contracted adjusts to this price.

Historical

Contract negotiations may be influenced by the results of previous negotiations. Disappointments or adverse consequences in previous years can affect current demands and bargaining power. Continued failure reduces the effectiveness of the organization as the organization is perceived by its members in a historical setting.

One difference in the effectiveness between marketing associations was felt to be historical. Ohio tomato growers had themselves formed an association on the basis of a felt need and later became affiliated with O.A.M.A. Some of the problems that face a new organization had already been overcome by then. In Indiana, on the other hand, the association had to convince farmers of their need for its program. At the time of the study, this group was at a different stage of development and was still going through the "growing pains" of increasing and consolidating membership and obtaining processor recognition. Its activities were thus somewhat different from those of O.A.M.A.

Organizational

There are many ways a group can organize, and this can affect its ability to bargain. The organizational form must facilitate communication from members to organizational leaders and vice versa; it must make the member feel an identification with the organization and a responsibility to it; and it must permit rapid decision making. Growers pointed to several problems in bargaining that are organizational in nature.[3]

Demographic

Farms are changing rapidly; they are becoming larger and more specialized. Some have felt this would improve farmer bargaining power, believing that more common interests might facilitate agreement about bargaining goals and methods. There was some evidence in this and another study [2, pp. 17–35] that the reverse might be the case; that is, that the larger farmer feels more independent and does not recognize the need for organization.

---

[3] On the 473 questionnaires, 324 growers responded to an invitation to make comments. Their remarks concerning problems in bargaining were classified as follows: lack of unity (27 percent), low membership (22 percent), organizational and leadership difficulties (12 percent), lack of processor recognition or unfair tactics (28 percent), and method of bargaining, mostly lateness of contract (11 percent).

Growers with larger operations had slightly less favorable attitudes toward bargaining and their associations. However, size of farm and degree of specialization were not significantly related to desired terms of trade or opinion of factors influencing bargaining power. Membership in organizations other than the marketing associations also was associated with attitudes toward bargaining. Grange members, NFO members, and members of milk cooperatives held more favorable attitudes toward bargaining than did growers not belonging to these organizations.

Attitudes toward bargaining

The bargaining parties' perception of the four factors discussed above in part shape their attitudes toward bargaining. Attitudes are also formed on the basis of expectations and realized results in previous periods. Relationships and behavior of parties during the actual process shape their attitudes about each other. Attitudes may give some indication of satisfaction with bargaining. More favorable attitudes toward bargaining and the rival may improve the chances for successful negotiation.

The attitudes of the three groups were obtained by means of a scaling device composed of a set of statements referring to the concept of bargaining or the association. Within each of these classifications, the statements were further subdivided as referring to economic or ethical aspects of the concepts. The economic aspect statements reflected considerations which might have an economic impact on the respondent. The ethical statements reflected the respondent's philosophical reaction to either the concept of bargaining or the association.

In comparing mean scores of attitudes among growers, grower representatives, and processors, the latter group was found to be significantly less favorable in their attitude toward bargaining and the bargaining association (Table 2). The higher scores compiled by committeemen as compared with growers, suggest they may be more dedicated members. Their scores may have been affected by their service on the committee, or they may have been elected because of more favorable attitudes. All groups compiled slightly more favorable scores on the concept of bargaining than on their association attitudes. In the case of growers and their representatives, this suggests a gap between expectations and performance. The scores on ethical aspects of bargaining and the association were more favorable than scores on economic aspects. This suggests that the different groups are not opposed to bargaining or the associations on philosophical

Table 2. Comparison of growers, grower representatives, and processors in their attitudes toward bargaining and the bargaining association

	Attitude scores[a]		
	Growers	Committeemen	Processors
Bargaining attitude			
Economic aspects	4.08	4.30	2.90
Ethical aspects	4.09	4.29	3.03
Association attitude			
Economic aspects	3.34	3.58	2.61
Ethical aspects	3.75	4.13	2.76

[a] Values less than 3 reflect an unfavorable attitude and values greater than 3 a favorable attitude, based on four classifications of 20 attitude statements which could take on values from 1 to 5.

grounds. Rather, processors are more concerned about the economic impact of bargaining, and growers seem more skeptical about economic gains than about ethical aspects of the technique.

A comparison was made between attitudes of processors who had refused and those who had not refused recognition of the association. Attitude scores of the processor, of growers delivering to the processor, and of the grower committee negotiating with the processor were all much higher when a contract had been negotiated. This supports an attitude formation theory that favorable bargaining experiences result in more favorable attitudes, which in turn make the process work more smoothly.

Bargaining strength

Bargaining processors, grower representatives, and growers were asked to rank factors contributing to their respective bargaining power. Significant agreement was found in each group.

Processors and grower representatives felt that control over the supply of tomatoes was the most important factor, while growers attached much importance to the skill of negotiators (Table 3). Processors attached more importance to their ability to pass raw product price increases to the next level forward than did growers or their representatives. All groups attached relatively low weights to the ability of one party to offer advantages to the other for accepting its proposal.

Bargaining environment

Bargaining processors and grower representatives were asked to rank factors affecting the ability of parties to reach agreement (Table 4). Both parties attached most importance to the information possessed by the respective parties. The processors felt that the willingness of parties in ne-

Table 3. Comparison of growers, grower representatives, and processor in their ranking of factors contributing to bargaining power

Factor	Pooled ranking[a]	
	Growers	Committeemen
1. Control over the supply of tomatoes by the association	4	2
2. Unity and loyalty of growers	1	1
3. Ability to offer advantages to the processor for accepting proposal	3	3
4. Ability of processor to pass price increase on to the next level	5	5
5. Skilled and informed association negotiators	2	4

Factor	Processor
1. Flexibility of processing alternatives both locally and in other plants	2
2. Alternative sources of supply (non-member or other production areas)	1
3. Ability to offer advantages to the cooperative for accepting proposal	4.5
4. Skilled and informed processor negotiators	4.5
5. Cohesiveness of processors in area	6
6. Ability to pass price increase to next level	3

[a] Value of Kendall's coefficient of concordance for growers' rankings was .167, for committeemen it was .343, and for processors it was .415. All coefficients were significant at the five percent probability level.

Table 4. Comparison of grower representatives, and processors in their evaluation of factors affecting the ability of parties to reach agreement

Factor	Pooled ranking[a]	
	Committeemen	Processor
1. Compatibility of people doing the negotiating	3	4
2. Willingness of opponents in negotiation to offer something in return for their demands	4	2
3. Level of information each side has concerning why opposite side has taken its position	1.5	3
4. Information each side has about economic considerations of tomatoes	1.5	1
5. Results of previous negotiations	5	5

[a] Value of Kendall's coefficient of concordance for committeemen was .141 and for processors it was .312. Both coefficients were significant at the five percent probability level.

gotiation to offer something in return for their demands was more important than did the grower representatives. Both sides attached relatively little importance to the compatibility of the negotiators or the results of previous negotiations.

Discussion of Results

1. The hypotheses previously stated were accepted, with the following exceptions: (1) growers and their representatives in O.A.M.A. did have common objectives, while those in I.A.M.A. did not; and (2) grower objectives and attitudes do not vary significantly according to certain farm characteristics.
2. Compared with O.A.M.A., I.A.M.A. was probably in less desirable circumstances with respect to influencing the terms of contract, for the following reasons: (1) lack of a large, well-disciplined membership who controlled a large percentage of the tomato acreage available; (2) a less favorable supply elasticity for tomato acreage; (3) more processors who did not want to become involved with bargaining or did not believe the association had anything to offer if they did negotiate; and (4) a poorer history of performance, in part due to its stage of development, which produced less favorable member attitudes toward bargaining. In addition, legislative and legal activity by O.A.M.A. had resulted in a better bargaining environment for the association in Ohio.
3. Indiana committeemen ranked improved grading first and higher prices third, whereas the growers they represented ranked higher prices first and improved grading second. Lack of common objectives may have adversely affected I.A.M.A. bargaining efforts.
4. Growers place too little emphasis on supply management, in view of their response to higher prices. They overrate the power of skilled negotiators. This may be a case of hope versus experience. Growers hope that control of supply is unimportant and that skilled negotiators are important, because this is the route to easy solutions. Committeemen know better. The associations will have to increase their educational and other efforts concerning control of supply if they are to increase their bargaining power. They may need to establish alternative outlets or processing facilities in order to better manage or utilize the supply of tomatoes.
5. Further work is needed to estimate supply and demand relations, since this information is needed by all parties. Incorrect information about economic factors can make negotiations more difficult and result in undesired and unexpected consequences from the terms agreed upon.
6. Information played a key role in the bargaining process. Processors seem better informed about market conditions and acreage; and there have been differences of opinion about some of the information used, such as cost of production. The bargaining process would operate more smoothly if both parties had the same information; this would eliminate conflicts about accuracy and make objectives more realistic. It suggests the development of an information system for joint use, perhaps by an outside agency.

7. A more formalized process for conducting the negotiations could eliminate some of the problems encountered. A time deadline is essential, so that negotiations do not extend into the planting season, as has sometimes happened. Should this deadline be reached before negotiations are concluded, mediation or arbitration might be utilized to resolve any remaining conflicts. A formalized agreement to bargaining each year would eliminate much of the uncertainty surrounding the establishment of a contract and would allow the parties to negotiate over genuine points of difference rather than spend time determining whether there was to be a negotiation.
8. Both parties to the bargaining process should try to accommodate the primary needs of the other and attempt more integrative bargaining. Processors seem to be primarily concerned with quality factors; growers, with price. This suggests that a "trading off" of concessions would benefit both sides.

Cash-Futures Price Relationships for Live Beef Cattle*

R. L. EHRICH

The objectives of this study, all pertaining to pricing efficiency, were: (1) to develop a theory of cash-futures price relationships for beef cattle; (2) to measure the factors that have affected cash-futures price relationships during the three years of trade in live-beef-cattle futures; and (3) to provide a framework for evaluating the efficiency of futures markets and hedging in the pricing of feeder cattle. Three types of evidence are employed to attain these objectives. First, the principles of cash-futures price behavior derived from observation of long-established futures markets serve as points of departure, while consideration is given to certain fundamental differences that arise from contrasting commodity characteristics. Second, empirical results relating to supply and demand for feeder cattle are employed to define expected relationships between futures prices and prices of feeder cattle of various weights. Third, data generated by the beef cattle futures market itself are analyzed, although it is recognized that these data cover only a short time period and are therefore of limited usefulness.

Principles of Intertemporal Price Relationships

CASH-FUTURES price spreads are now recognized as a function of stocks in the case of seasonally-produced commodities that need to be stored and are storable in significant quantities. This price—the price of storage—is competitively determined by the supply and demand for storage in the same way as any other price. Moreover, like any other competitively determined market price, it tends to equal the marginal costs of production in the short run—production in this case referring to provision of the storage service.

These conclusions were developed by Working out of empirical studies of wheat prices and stocks [26 and 27], then elaborated in more recent theoretical articles [25, 29, 30]. Brennan expanded somewhat on the details of the makeup of marginal costs of storage and their relationship to observed price spreads [1]. Weymar has recently proposed extending the theory to include "expected inventory behavior over the intervening interval" between spot and futures dates [24, p. 1228].

Working's empirical studies of wheat [25, 26 and 27], Telser's study of wheat and cotton [18], Brennan's results for wheat and oats [1], and my results for spring wheat [6, pp. 65–74], all serve to substantiate the theory that cash-futures price spreads are a function of current inventories for annually produced, storable commodities, under conditions existing in the United States.

Hedging by owners of storage space, in reaction to the market-deter-

R. L. EHRICH *is associate professor of agricultural economics, University of Wyoming.*

mined price of storage, is the mechanism by which stocks are allocated into or out of storage over time. Such hedging is competitive arbitrage that tends to force cash and futures prices into a relationship consistent with the supply and demand for storage [25, p. 555].

Paul and Wesson have expanded the concept to include prices for services other than storage; namely, conversion of soybeans into products [13, 14] and cattle feeding [15]. In the case of soybeans, spreads between cash prices of soybeans and futures prices of oil and meal are viewed as competitively determined prices of the processing service. Similarly, the value of finished cattle, as determined by the price of a relevant futures contract, less the value of the feeder cattle and feed required to produce a finished animal on the delivery date, is the market value of feedlot services [15, p. 39]. This margin is competitively determined by the supply and demand for feedlot services and is "fairly independent of the commodity prices from which it is derived" [15, p. 39].

Paul and Wesson's conclusions are valid as far as they go, but the analysis was incomplete in a number of respects. First, it did not explain the behavior of price spreads, but merely described the expected spread between values. Second, lumping feed and feeder cattle together concealed an important relationship that theoretically should exist between feed prices, feeder-cattle prices, and expected fed-cattle prices. Third, while the spread between values is independent of the commodity prices from which it is derived, the spread between prices of feeder cattle and future prices of finished cattle is directly dependent on the level of futures prices. The latter conclusion will be shown to be a direct result of the nature of demand for feeder cattle.

The Demand for Feeder Cattle

Applying the reasoning of neo-classical firm theory to cattle feeding, it is clear that the quantity of cattle placed on feed should be a function of expected fed-cattle prices, feed prices, feeder-cattle prices, and prices of other factors of production. J. D. Goodwin quantified such a relationship in a recent study, using quarterly placements of feeder cattle on feed in thirteen states as the dependent variable [8]. His results were consistent with theory in that placements were an increasing function of fed-cattle prices and a decreasing function of corn prices and feeder-cattle prices [8, p. 24]. Feed is the single most important factor of production other than feeder cattle, so the price of corn served as a proxy variable for all factors of production other than feeder cattle.

Other evidence throws doubt on the validity of Goodwin's results. First, the statistical results do not hold when data for 1963–1966 are added to the analysis.[1] Second, annual marketings of fed cattle did not vary cyclically as did total commercial slaughter of all cattle (Figure 1).

---

[1] Goodwin used logarithms of quarterly data for 1955–1962. His regression co-

---

efficients were −.45230 for the price of feeder cattle, +.94890 for the price of fed steers, and −.91231 for the price of corn. All were significant at the one percent level of probability and R^2 was equal to .96 [8, p. 24]. Regression coefficients calculated after adding 1963–1966 were +0.09364, +1.06561, and +0.15604 for feeder-cattle prices, fed-cattle prices and corn prices, respectively, and R^2 was equal

Implications of the first evidence for the theory of demand for feeder cattle are obvious, but the second bit of evidence (Figure 1) requires elaboration. Absence of cyclical variation in marketings from feedlots suggests that the quantity of feeder cattle demanded has not responded to price expectations in past years, because since 1948 prices varied in a fairly regular cyclical pattern that was inverse to the variation of total commercial slaughter [7]. Prices of feeder cattle have responded to expected prices of the finished product, while quantity of feeder cattle demanded has apparently been affected primarily by feedlot capacity and its growth over time. The quantity of feeder cattle available depends on past prices and affects the price of feeder cattle indirectly through its effect on expected fed-cattle prices.

The above relationships were empirically tested and the results using annual averages of the variables for 1947–1964 were:[2]

$$(1)\qquad Pf = 0.146 + \underset{(.097)}{1.140Ps} - \underset{(.015)}{0.061If} - \underset{(.278)}{0.457\Delta Fn}, \qquad R^2 = .92;$$

where

Pf = annual average price of feeder steers at Kansas City ($'s/cwt.),
Ps = annual average price of choice slaughter steers at Chicago ($'s/cwt.),
If = index of prices received by farmers for feed grains (1957–59 = 100), and
ΔFn = annual change in January 1 inventory of beef calves, steers, and heifers, minus cattle on feed on January 1 (million).

Numbers in parentheses are standard errors of the regression coefficients. The coefficient for change in feeder-cattle supplies (ΔFn) suggests that pressure of increased supplies on existing feedlot capacity reduced the price of feeder cattle, given expected prices of feed and finished cattle.[3]

---

to .73. None of the above coefficients was significant at the *five* percent level of probability, and the signs of the coefficients for corn and feeder-cattle prices were the reverse of that predicted by theory.

[2] See [7, p. 24].

[3] The reverse was true for decreased supplies of feeder cattle. Equation (1) was also fitted with semi-annual data, adding a zero-one shift variable (S) and letting ΔFn be the same for January-June and July-December. The results were:

$$(1a)\qquad Pf = 1.2052 + \underset{(.0820)}{1.0354Ps} - \underset{(.0120)}{0.0398If} - \underset{(.2454)}{0.0410\Delta Fn} - \underset{(.5504)}{2.4290S}, \qquad R^2 = .85.$$

All coefficients were significant at the five-percent level of probability, except ΔFn. Data were not available before 1955 which would enable estimation of ΔFn for the July-December semester. If data had been available, it is expected that the fit would have been improved, and the coefficient of ΔFn probably would approach statistical significance.

In sum, the short-run demand for feeder cattle was manifest in feeder-cattle-price adjustments to expected fed-cattle prices and feed prices, while quantity demanded was largely a function of growth in feedlot capacity over the longer run.

The above demand function implicitly assumes that expected prices are equal to current prices for both the final product and feed; i.e., in the face of uncertainty, cattle feeders view current prices as their best indication of expected prices. The assumption is of course naive; individual producers undoubtedly formulate expectations in a more sophisticated manner, perhaps even employing simple statistical models to project prices.[4] However, producers' response to uncertainty in the aggregate may well result in patterns of price-quantity relationships commensurate with the naive model. Recursive models of the livestock industry have generally employed lagged price in their supply functions with quite acceptable results in the aggregate.[5] Beyond that, use of more sophisticated models of price expectations must await their further development and testing.

Cash and Futures Price Relationships

Assuming that producers view current fed-cattle prices as their best estimate of expected prices and that purely competitive conditions prevail in the beef-cattle feeding industry, the following equation describes industry equilibrium:

$$PsWs - PfWf - C(Ws - Wf) = 0 \tag{2}$$

where

Ps = current price of fed steers
Pf = current price of feeder steers,
C = total costs of feeding per cwt. of gain,
Ws = finished weight of steers, and
Wf = beginning weight of feeder steers.

Costs (C) include a "normal" profit, giving a zero net return in long-run equilibrium.

If equilibrating forces are operative, a change in price of fed cattle (Ps) will cause prices of feeder cattle to change in the same direction, given the beginning weight of feeder cattle and constant costs of gain. Given Ps, Ws and Wf, a change in C will require Pf to change in the opposite direction. Finally, heavier-weight feeder cattle will receive a lower price than lighter-weight feeder cattle, given that Ps, Ws, and C are held constant. Equation (2) thus provides logical support for the results of equation (1).

---

[4] Nerlove examined several alternative models of producers' price expectations in [12].

[5] For examples: Harlow used lagged price to estimate a supply function for hogs as part of a cobweb model of the hog cycle [9]; Larson utilized a variant of lagged price to explain supply response in a harmonic motion model of the hog cycle [10]; and Waugh discussed cobweb models as a class, generally concluding that they are useful for predictive purposes [23].

Manipulation of equation (2) provides clearer insight into expected relationships among prices in equilibrium, assuming constant beginning and ending weights (Ws and Wf). Adding $PSWf$ to both sides of equation (2),[6] combining terms, and simplifying, we have:

$$Ps - Pf = (Ps - C)\left(1 - \frac{Ws}{Wf}\right). \tag{3}$$

Assuming that $Ws = 1000$ pounds and $Wf = 600$ pounds, (3) reduces to:

$$Ps - Pf = -\tfrac{2}{3}(Ps - C). \tag{4}$$

Given the assumed weights, the spread between expected fed-cattle prices (Ps) and feeder-cattle prices (Pf) will be negative if $Ps > C$. If $C > Ps$, then $Ps - Pf > 0$. As Ps increases, $Ps - Pf$ becomes a larger negative number, i.e., Pf increases at a greater rate than Ps. As C increases, $Ps - Pf$ becomes a smaller negative number and eventually becomes positive.

Substituting the price of cattle futures (Ps^*) for Ps in equation (3), we have:

$$Ps^* - Pf = (Ps^* - C)\left(1 - \frac{Ws}{Wf}\right), \tag{5}$$

which describes the forces that affect the cash-futures price spread for beef-cattle, given that the quantity of feeder cattle placed on feed is not appreciably affected by expected prices (equation (1)); i.e., given that prices of feeder cattle adjust to expected prices of fed-animals, while feeder-cattle placements depend primarily on feedlot capacity.

Equation (5) may be stated in other terms, to clarify the nature of market forces which theoretically affect the spread between cash and futures prices. Ps^* is the market determined expected price of fed cattle for delivery at a specified future date. If this price is sufficiently high relative to current feeder-cattle prices (Pf) and costs of feeding, the cattle feeder may sell futures as a hedge, thereby fixing his profit position within rather narrow limits. Such action by many producers acts as competitive arbitrage, theoretically forcing the spread between cash and futures prices to reflect costs of feeding, as indicated by equation (5).

---

[6] See [17, p. 641] for a demonstration of the use of this manipulative procedure in another context.

Empirical Tests of Cash-Futures Price Relationships for Beef-Cattle

Beef-cattle futures have been traded for a very short time period, so empirical results must be viewed as somewhat tentative. However, it will be demonstrated that, while the evidence is not sufficient to prove the hypotheses that were developed above, it definitely does not provide grounds for rejecting them, nor does the evidence suggest better alternative hypotheses.

Selection of data representative of feeding costs (C in equations (2)–(4), above) presents a difficult problem because feeding programs vary widely among states and regions. Consequently, choice of data is necessarily somewhat arbitrary. Feeding rations, time-on-feed, non-feed costs, etc., are based on Van Arsdall's results [22] for selected feeding programs that may be considered typical for the cornbelt region.[7] Feed prices used to determine the total cost of feed are average prices received by farmers in Iowa and Nebraska. It is recognized that costs based on cornbelt conditions are probably not representative of costs for commercial feedlot operations in the western and plains states. However, data for the latter type of operation are not readily available in sufficient detail; and at any rate, for purposes of this analysis, the discrepancy should not bias the results.

The feeder-cattle price variable is measured as the weekly average price of choice 550–750 pound steers at Omaha. The futures-price variable is the weekly average price of Chicago cattle futures, calling for delivery six months after the date applicable to the feeder-cattle price, and discounted $.75 per hundredweight to obtain an Omaha basis. Averages were calculated for the week closest to the 15th of the month.

Spreads between feeder-cattle prices and the relevant futures prices are plotted in Figure 2 against per-head costs of feeding for each month from January 1965 through November 1967. Three facts are notable. First, cash-futures spreads and feed costs were apparently unrelated during January 1965 through February 1966 (open circles). This could reasonably have been expected because trade in futures during early months was light. Therefore, prices probably were not truly representative of economic conditions in the cattle feeding industry.[8]

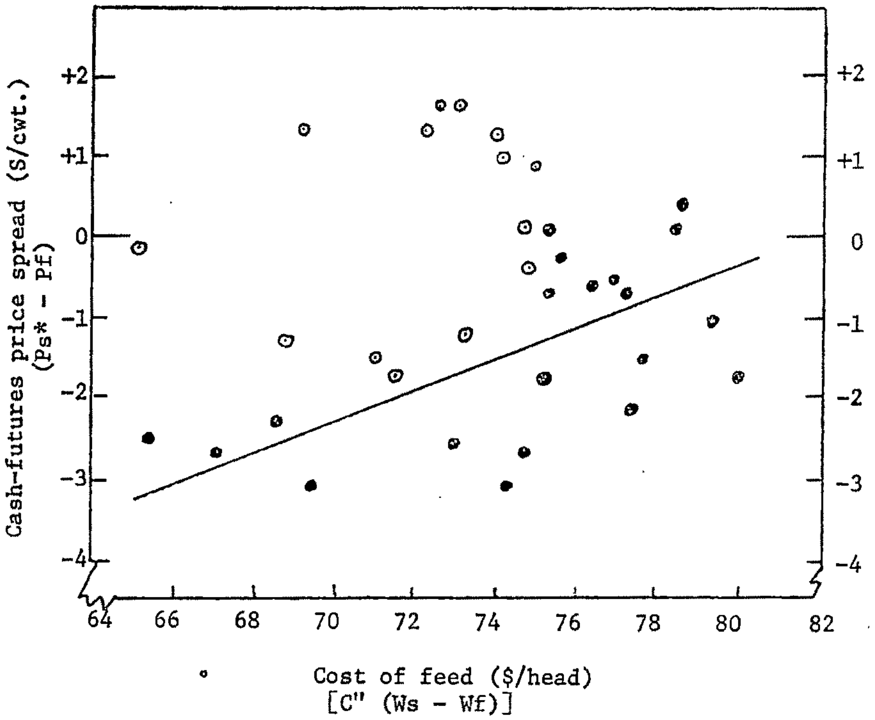
---

[7] Feed rations and costs used in this study are based on a feeding program wherein 675-pound choice steers are fed for a 180-day period to a market weight of 1080 pounds, in a feedlot with an annual capacity of 240 cattle [22, p. 10].

[8] The average level of month-end open contracts in beef-cattle futures for selected time periods was as follows [3]:

Period		*Av. Level of M.E.O.C.*
1965	Jan.–June	2444
	July–Dec.	4210
1966	Jan.–Dec.	11350
1967	Jan.–Nov.	20205

Figure 2. **Relationship between cash-futures price spreads and feed costs, monthly, 1965–1967**[ab]



Sources of basic data: Cattle prices from [20] and [3]. Feed prices from [21] and rations based on [22, Table B-11].

[a] Spread between weekly average price of choice 550–750 pound feeder steers at Omaha and weekly average price of Chicago live-cattle futures for delivery six months hence. Averages were calculated for the week ending closest to the 15th of each month. The futures price was discounted by $.75/cwt. to put it on an Omaha basis. Feed costs were calculated basis Iowa and Nebraska prices for a ration appropriate for 650-pound steers fed to a weight of 1100 pounds.

[b] Open circles indicate January, 1965, through February, 1966. Closed circles indicate March, 1966, through November, 1967.

The second notable fact is that the cash-futures spread was negative in all months except three during the later time period (March 1966 through November 1967). This is consistent with the prediction of equation (5), above, which says that if futures prices (*Ps**) exceed total per hundredweight costs of feeding (*C*), then the equilibrating mechanism will force the price of feeder cattle above the expected price of fed cattle, given constant beginning and ending weights (*Ws* and *Wf*). Per hundredweight costs of feeding were generally below the expected price of fed animals during the period, judging from Van Arsdall's cost estimates.

Third, the cash-futures spread tended to become less negative as feed costs increased, which again is consistent with the hypothesis contained in equation (5). The fit was not particularly good (Figure 2), making it necessary to qualify the conclusion somewhat. The relatively wide scatter of observations around the hand-fitted regression line was probably caused by two factors. First, monthly data are affected by short-term disturbances associated with the process of price discovery; i.e., prices are generally in disequilibrium because the emergence of pertinent market information tends to occur in a random manner.[9] Second, trade in futures still represents a relatively small proportion of total cattle placed in feedlots in the United States, so forces affecting feeder-cattle prices are probably not fully reflected in futures prices. For example, a large segment of the cattle feeding industry probably persists in viewing current and past "cash" prices as the best available indication of expected prices, thereby disturbing the expected relationship between cash-feeder-cattle prices and futures prices.[10]

Cash-futures spreads are related directly to the spread between futures prices and total per hundredweight costs of gain in Figure 3. Costs are again based on Van Arsdall's data for a 180-day feeding program, adjusted to reflect a beginning weight of 650 pounds and a finished weight of 1100 pounds, and are applicable to a feedlot with a capacity of 240 cattle per year. The upper line of the chart represents the cash-futures price spread necessary to cover all variable costs including feed. For example, if $Ps^* - C = -\$2.00$/cwt., the breakeven cash-futures spread ($Ps^* - Pf$) is $-.69\ (Ps^* - C)$, or +$1.38/cwt. The coefficient $-.69$ is derived from the element $(1 - Ws/Wf)$ of equation (5), above, assuming $Ws = 1100$ and $Wf = 650$.

As predicted by equation (5), the cash-futures spreads tended to become increasingly negative as futures prices increased relative to costs of gain (as $Ps^* - C$ grew larger). The scatter of observations around the "variable cost" line appears random, a fact again consistent with accepted economic theory, which says that short-term market disturbances tend to occur in a random manner.

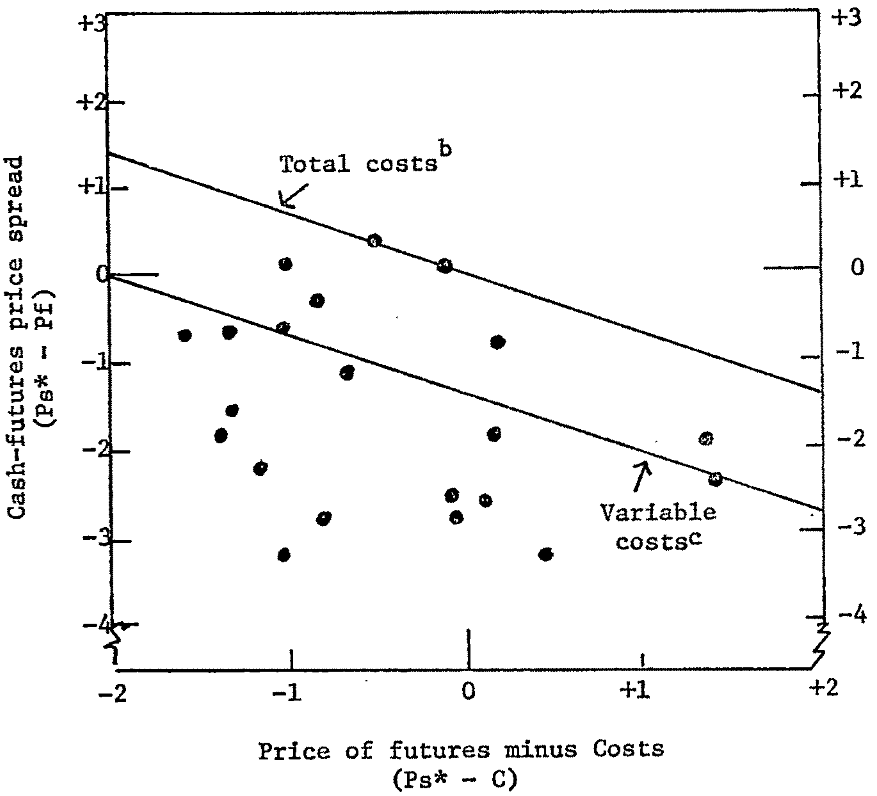
---

[9] See [11] and [28]. The former is a statistical analysis of daily prices which indicates that short-term price changes behave as a random walk. The latter reference presents a theory of anticipatory prices which, in essence, says that changes in expected prices depend on market news, and new market information tends to occur randomly. Thus, prices continually react to market news, given uncertain future events, producing a short-term price pattern that resembles a random walk.

[10] Still another factor may be seasonal variation in non-feed costs, which costs were not included in the cost variable presented in Figure 2. This factor cannot be tested, because data on seasonal variation in non-feed costs are not available. However, the scatter of observations around the hand-fitted line in Figure 2 had no identifiable seasonal pattern. This suggests that seasonal variation in non-feed costs probably was not a factor contributing to the deviation of individual monthly observations around the regression line.

Figure 3. Relationship between cash-futures price spreads and futures price-cost spreads, monthly, March, 1966, through November, 1967[a]

($'s/cwt.)



Sources of basic data: See footnotes, Figure 2.

[a] Prices are as described in footnote a, Figure 2. C is equal to feed costs plus total non-feed costs. The latter costs were taken from [22, pp. 38 and 58].

[b] Computed as $Ps^* - Pf = -.69(Ps^* - C)$, where C is total costs per hundredweight and other variables are as previously defined.

[c] Computed as $Ps^* - Pf = -.69(Ps^* - C^1)$, where C' includes all variable costs and other variables are as previously defined.

Conclusions regarding the relationship between cost levels and cash-futures price spreads should be made with caution, because the cost data used here may not represent a minimum-cost situation. It is expected that competition will force the price spread toward the break-even point for the lowest-cost firms, if most cattle are fed in low-cost feedlots. Assuming that the break-even level for minimum-cost firms is lower than that represented in Figure 3, the pattern of observations in Figure 3 suggests that cash-futures price spreads tend to vary around equilibrium in a manner consistent with the purely competitive model. That is, the average spread between cash and futures prices over longer periods tends to equal total costs of feeding including a normal competitive profit. Conditions of pure competition are defined here to include the usual assumptions regarding numbers of firms and homogeneity of product. Additional assumptions are that uncertainty exists, market information emerges in a random manner, and a time lag is required for adjustment to disequilibrium.

Another difficulty of interpretation of the relationship between costs and cash-futures spreads is caused by the fact that prices of feeder cattle represent choice animals. It is likely that a significant number of cattle feeders purchase "plainer" types of feeder cattle and still market choice fed-cattle. Thus, a bias of unknown magnitude may exist in the size of the cash-futures spread, relative to costs of feeding. For this reason, and because the available cost data may not represent true industry cost levels, firm conclusions regarding the level of costs that are expected to be reflected in cash-futures spreads must await further research.

These reservations notwithstanding, the scatter of observations about the cost lines in Figure 3 suggests an important conclusion with respect to expected short-term price behavior in beef-cattle futures markets. At any given point in time, market prices will tend to be in disequilibrium, owing to random disturbances such as new market information, and will be changing in response to such information, presumably in the direction of equilibrium.

Although the data are not wholly adequate for an analysis of price behavior, certain patterns of dynamic price adjustment are at least suggested by weekly data derived in the same manner as the monthly data discussed above. These data provide a partial test of the hypothesis that cash-futures price spreads adjust toward a "break-even" relationship, in a direction commensurate with its dislocation from the "break-even" or equilibrium point in a previous time period. Gross returns per hundredweight for feeding cattle, as indicated by the cash-futures price spread minus variable costs of feeding, were compared to weekly changes in cash and futures prices during the following month.[11] The results are summarized in Table 1.

---

[11] For example, net returns over variable costs for feeding cattle (R) are calculated as follows, using monthly average values of the variables:

$$Ps^*Ws - PfWf - C'(Ws - Wf) = R,$$

where Ps^*, Pf, Ws and Wf are as defined above, and C' is total variable cost per hundredweight, other than the cost of the feeder cattle. R is then related to the change in feeder-cattle prices and relevant futures prices during the four weeks following the month applicable to R.

Table 1. **Monthly average returns from cattle feeding, as indicated by the cash-futures price spread, compared to the change in cash and futures prices during the following four-week period, January 1966 through November 1967**

($'s/cwt.)

Item	Level of Returns[a]					
	Low	Medium	High	Low minus medium	Low minus high	Medium minus high
Average change in futures price[b]	+.19 (.28)	−.12 (.33)	−.41 (.27)	+.31 (.44)	+.60 (.40)	+.29 (.84)
Average change in feeder-cattle price[b]	−.40 (.16)	+.16 (.07)	+.46 (.30)	−.56 (.18)	−.86 (.32)	−.30 (.27)
Number of months in the average	8	8	6	16	14	14

Sources of basic data: See footnotes, Figure 2.

[a] The range of monthly profit levels (22 total) was as follows:

Low = −$5.46 through +$4.37 per head,
Medium = +$8.40 through +$14.24 per head,
High = +$16.05 through +$32.62 per head.

[b] Numbers in parentheses are standard errors of the means and mean differences, respectively.

When monthly average returns were low, feeder-cattle prices declined by an average of $.40/cwt. during the following four-week period. Futures prices tended to rise following low-returns months, but the average change was not statistically different from zero. Feeder-cattle prices increased by an average of $.16/cwt. and $.46/cwt. during the four weeks following months of medium and high returns, respectively. Again, futures prices tended to decline following high-profit months, but the average change was not significantly different from zero.

The rather limited data presented in Table 1 clearly indicate a tendency for feeder-cattle prices to adjust toward equilibrium ("break-even" level) as predicted by the hypothesis, while adjustment in futures prices was less consistent with the hypothesis. The evidence shows fairly clearly that competitive forces tend to cause feeder-cattle prices to adjust relative to the relevant futures price in a manner consistent with the assumptions of pure competition, given uncertainty regarding future events. Periods of disequilibrium tend to be followed by adjustments toward competitive equilibrium.

Conclusions and Implications for Pricing Efficiency in the Beef-Cattle Market

Demand for feeder cattle is manifest in adjustment of current feeder-cattle prices to expected fed-cattle prices, costs of feed, and changes in available feeder-cattle supplies. Current placements on feed tend not to respond to price relationships, but are governed in the short run by feedlot capacity. Feedlot capacity has trended upward since 1948, reflecting favorable average profits in the cattle-feeding industry since that time.

These structural demand characteristics for feeder cattle provide a framework for construction of a theory of cash-futures price relationships for beef cattle. Under purely competitive market conditions, cash prices of feeder cattle and futures prices will bear a relationship to one another which is determined by costs of feeding and the level of futures prices. In competitive equilibrium the following equation holds:

$$Ps^* - Pf = (Ps^* - C)\left(1 - \frac{Ws}{Wf}\right).$$

Judging from empirical evidence, it is concluded that this equation is the appropriate model of cash-futures price relationships for beef cattle. Observed price spreads varied around predicted equilibrium in a manner consistent with behavior in a purely competitive market, given uncertainty regarding future events. Weekly changes in feeder-cattle prices were consistent with the prediction of the theory. Hedging by cattle feeders is the competitive mechanism by which these price adjustments are made in the market-place.

A major problem remains regarding an appropriate concept of costs (C). Presumably, competition will force price spreads into line with the cost structure of low cost firms. However, a definitive statement regarding the expected relationship between levels of cost and levels of cash-futures spreads must await further research.

Certain conclusions about expected price behavior and pricing efficiency are possible in view of the results of this study. Cash prices of feeder cattle are tied by economic forces to prices of futures contracts. Specifically, the cash-futures price spread is the market price for cattle-feeding services, and as such coordinates decision making in the industry. However, unlike the case of storable commodities, where cash-futures spreads signal adjustments in quantity stored, it is not expected that quantities placed on feed will adjust to cash-futures price spreads for beef cattle. Rather, the price of feeder cattle will adjust to expected fed-cattle prices, the latter being determined by inventories of available feeder cattle and expected demand.

One major implication of the last conclusion is that the existence of futures markets will facilitate more efficient adjustment of feeder-cattle prices to feeding costs and price expectations. In the absence of a market-determined expected price, uncertainty most probably forces discounting of the future, with consequently inefficient adjustment in prices paid for feeder cattle. Futures trading may remove much of this pricing inefficiency.

Several questions requiring additional research are suggested by the analysis. What cost elements in the cattle-feeding industry are important for predicting the behavior of cash-futures price spreads? Will the existence of a futures market precipitate significant adjustments in the structure of the cattle feeding industry? In particular, will cash-futures spreads tend to reflect the cost structure of highly efficient, large-scale commercial feedlots, thereby forcing smaller farmer-feeders out of the industry? Finally, what, if any, are the implications of futures trading regarding prices received by producers of feeder cattle? For example, will producer-prices approach a competitive ideal and if so, will this change the economic structure of the feeder-cattle production industry?

The Allocation of Research, Teaching, and Extension Personnel in U.S. Colleges of Agriculture*

Willis L. Peterson

The aim of this paper is to inventory the allocation of research, teaching, and extension personnel by departments in United States colleges of agriculture and experiment stations, and to identify and measure factors that appear to influence this allocation. Although growth is the predominate characteristic of departments and disciplines, we observe and can predict decline in several instances. With the use of multiple regression analysis, state nonfarm income emerges as the most important variable explaining total funds available to experiment stations. Rural farm population has virtually no effect on total funds available. In fact, since 1960 it was somewhat of a detriment for an agricultural experiment station to be located in an agricultural state. At the departmental level, the departments engaged in farm oriented research (agronomy, animal husbandry, etc.) appear to be more dependent on farm income for support whereas departments in closer contact with the nonfarm sector (horticulture, agricultural economics, etc.) are more dependent on nonfarm income. Predictions for the early 1970's indicate largest growth for departments located in the high income, urban-industrial states particularly for those more closely tied to nonfarm income.

THE growth in technology and productive efficiency of U.S. agriculture is a well-known fact. Moreover, there seems to be little doubt that the research, teaching, and extension activities of U.S. land grant colleges and experiment stations have contributed greatly to making this productivity growth possible. In fact, we are accumulating evidence which indicates that the social rate of return to investment in these activities is high, relative to the rate of return obtained from typical investment alternatives [2, 3, 7]. This would suggest that there has not been an over-allocation of resources devoted to the production and distribution of knowledge in U.S. agriculture.

As in any other production activity, we are concerned not only with the total amount of resources devoted to research, teaching, and extension, but also with the most efficient mix of resources in each. For example, would the social return to agricultural research be higher if less resources were allocated to crop research and more to livestock research, or vice versa? Before questions of this nature, i.e., what should be, can be answered, it seems that we must know first, what is.

Keith Bryant, Robert Evenson, John Helmberger, Vernon Ruttan and the participants of the policy workshop in the department, without implicating to them any shortcomings of the paper.

Willis L. Peterson *is assistant professor of agricultural economics, University of Minnesota.*

The main objectives of this paper are (1) to inventory the allocation of research, teaching, and extension personnel by departments in U.S. colleges of agriculture and state agricultural experiment stations and (2) to identify and measure factors that appear to influence this allocation. Major attention will be devoted to the research and teaching.

The Data

The main source of data is the annual USDA publication, "Professional Workers in State Agricultural Experiment Stations and Other Cooperating State Institutions" [11],[1] which gives a simple head count of the number of professional people in each department. The data were collected for each state, but because of space limitations only U.S. totals are presented in Tables 1 and 2. These figures include only faculty of the rank instructor or research associate and higher, excluding supporting staff and graduate students. An attempt was made to separate teaching and research from extension, which accounts for the fractions in the data. For example, an individual involved in teaching, research, and extension was counted as two-thirds teaching and research and one-third extension. Since a majority of the personnel are listed either as teaching and research only or as extension only, the figures probably are not seriously biased by this procedure.

Table 1. Number of teaching and research personnel and percent distribution by years, U.S. colleges of agriculture and experiment stations

one department. The same was true of Agricultural Economics and Rural Sociology. As departments grew, there was a tendency for some disciplines to split off and become autonomous units, but this tendency seems now to be reversing itself. In the 1960's there has been a trend towards consolidation, as in the livestock areas where some dairy, animal husbandry, and poultry units are merging into animal science departments. Fortunately, since most individuals in multi-discipline departments are identified by field of specialization, it is possible to make a reasonably consistent inventory of departmental personnel in spite of this separation and merging of disciplines.

These data have value because they provide a cross-section inventory of the teaching, research, and extension work within each land grant college and experiment station, information not published in summary form prior to 1966. The 1967 USDA report, "An Inventory of Agricultural Research," presents scientific man-year and expenditure figures for 91 problem areas for 1966 in state agricultural experiment stations, forestry schools, and research agencies of the USDA [9].

To be sure, both the USDA figures and the personnel data presented in this paper have limitations. For one thing, the latter do not reflect with 100 percent accuracy differences in expenditures between departments because of salary differences and differences in supporting facilities and personnel. Also, because no data are available on numbers of graduate students, the amount of research carried out may not be perfectly reflected by the number of research and teaching personnel. Moreover, it is not possible to determine how personnel time is apportioned between teaching and research.

The research expenditure and man-year figures of the USDA report have other drawbacks. First, it is not certain that all funds earmarked for research are actually used for this purpose. One must suspect that in some departments research subsidizes teaching or in others just the opposite may be true. Second, it is often difficult to distinguish teaching from research, as in the supervision of a graduate student's thesis research. Since teaching and research are so closely related at the graduate level, it seems futile to attempt a separation.

Finally, it would be naive to believe that research expenditures are used 100 percent on the problem areas for which they are reported. Because of political pressure, changes in public sentiment regarding urgent problems, and the like, the earmarking of research money to a given problem area may not coincide with the actual use of these funds by scientists. Fortunately, this problem does not come up with department-wide classification, which is one advantage of the personnel data. Perhaps the main advantages of the personnel data, however, are that they coincide with the administrative units in experiment stations and allow us to study changes in the allocation of research, teaching and extension resources at the state and national level over a long period of time.

Allocation in the Aggregate

As might be expected, the predominant characteristic of the data presented in Tables 1 and 2 is the long-run growth in number of personnel, by disciplines. It is of interest, therefore, to note some exceptions to the rule. In terms of teaching and research personnel, Dairy and Agricultural Education exhibit a noticeable decline during the 1960–67 period while Poultry remains about constant. During the 1930–35 period (not shown in the tables), six of the twelve disciplines—Agricultural Economics, Agricultural Education, Agronomy, Dairy, Poultry, and Soils—declined in numbers of teaching and research personnel.

The rate of growth of extension personnel exceeded that of research and teaching in the 1960–67 period—2.9 percent per year for extension compared with 1.7 percent per year for teaching and research. Also, none of the disciplines experienced a decrease in extension personnel during this time. In the depression years, however, extension did not fare as well as teaching and research. With the exception of Agricultural Economics, Animal Husbandry, and Horticulture, all disciplines reduced their extension personnel, and the last two remained about constant.

The big exception is Agricultural Economics extension, where the number increased from 95 in 1930 to 160 in 1935 a rate of growth unsurpassed anytime since then. Very likely, government programs to alleviate the decline in relative farm income at that time provided the support for this large increase. The hypothesis that total number of Agricultural Economics extension personnel is inversely correlated with relative farm income is supported by the record of more recent periods also. During the 1940–50 decade, Agricultural Economics extension experienced virtually no growth whereas in the 1950's and 1960's the growth rate was substantially higher than the U.S. average for all extension. More will be said about the relationship between income and department size in the next section.

Another predominant characteristic is the relative stability of shares allocated to each discipline over the long-run. Disciplines that were given a large slice of the pie in 1930 were still receiving it in 1967, with a few exceptions. Agricultural Education is perhaps most notable in teaching and research, declining from 6 percent of the total in 1930 to 2 percent in 1967. Dairy and Horticulture also lost, in relative terms. On the other hand, it is difficult to explain the large relative size of Horticulture in the 1930's. Perhaps its recent decline indicates a movement towards an "equilibrium" rather than a relative reduction in its emphasis on teaching and research. Soils exhibits the largest relative increase, moving from 6 percent in 1930 to 10 percent in 1967.

In the area of extension, Agricultural Economics stands out both as the largest in 1930 and as the one that experienced the most growth up to the present, although its growth in relative size took place from 1930 to 1935. Soils and, to a lesser extent, Agricultural Engineering also experienced some relative growth during the 1930–67 period. Poultry and Dairy exhibited the largest relative decline over the 1930–67 period.

Of course, the trends in the aggregate figures cover up many changes in individual departments. Although most disciplines grew in absolute numbers, it is not uncommon in any one year to find that some individual departments decreased in size. With the long institutional background of most departments, decline is no doubt a painful process. Merging a department that is declining with one or more larger departments seems to be a fairly common procedure.[2] This probably makes the adjustment process a little easier for the declining department and reduces administrative overhead at the same time.

Factors Influencing Allocation

We now enter an area where conjectures abound but where rigorous, quantitative analysis is in short supply. With a little reflection, it is possible to think of several explanations for differences in growth and size, both at the experiment station level and at the department level.

---

[2] Merger does not affect the way in which personnel are reported in this paper. For example, if a poultry department merges with animal husbandry to form one animal science department, the personnel are still reported with their former departments.

Experiment station level

The amount of money made available to an experiment station each year, of course, is the ultimate determinant of its size. Federal funds are allocated largely on a formula basis [12, p. 232].[3] Twenty percent is allocated equally to each state. Not less than 52 percent is allocated on the basis of the size of each state's rural population and farm population relative to total U.S. rural and farm population And not more than 25 percent is allocated to the states for cooperative research in which two or more experiment stations participate on a common problem.

Nonfederal funds, the other major source, have accounted for about 75 percent of total funds available to experiment stations in recent years.[4] The amount of these funds forthcoming to a given experiment station is largely determined by the state's tax base and its willingness to tax. Thus, we might hypothesize that differences in income of the states would be an important variable explaining differences in nonfederal and total funds available to experiment stations.[5] Of course, if we are interested only in predicting funds available in year T, the best predictor would be funds available in year T-1. In the case of a public institution where the majority of personnel have a lengthy, specialized training period and are not subject to layoffs, short-run changes in size are, at most, marginal.

Department level

At the individual department level, we have evidence of both growth and decline. But here as well there is no shortage of explanations. The degree of leadership exercised by the department head and the predisposition of the experiment station director toward the department would matter at least in the short-run. The competence of a department in urgent and important problem areas is likely to be another factor. The rapid growth of Entomology in the grasshopper-infested Southwest and West in the 1930's is one example of this phenomenon. Nor is the decline of Poultry and Dairy departments totally unexpected in states where the two related industries are declining.

Although a single department takes up only a small fraction of an experiment station's annual budget, it can be argued that the income of the state is still important. A reduction in state appropriation because of high unemployment and revenue loss, for example, is generally not borne by one or even a few departments. Poverty or affluence, as the case may be, is generally shared across the entire experiment station. The relative constancy of discipline shares over time bears evidence to this. This is not to say, however, that all departments exhibit the same relationship to income.

---

[3] Federal funds include mainly Hatch Act funds, regular plus regional research. These funds made up 90 percent of federal funds in 1966. Also included are funds appropriated by the McIntire-Stennis Act and special grants by the federal government for research and facilities.

[4] Non-federal funds include mainly state appropriations, which made up about 70 percent of nonfederal funds in 1966. Also included are grants from foundations and industry, about 7 percent of total nonfederal funds in 1966. Revenue from fees and sales made up about 13 percent of nonfederal funds in 1966. Fees and sales are not included in the analysis, however, unless specifically stated.

[5] The formulation of this hypothesis should be credited to T. W. Schultz [8, pp. 60–72].

Regression equations and results

In this section, the farm and nonfarm components of state personal income are used as explanatory variables in regression equations in an attempt to explain differences between states in size of experiment stations and departments. Also, the effect on department size of farm production that is closely related to specific departments is estimated. To allow for adjustment time and year to year fluctuations in the income and related farm production variables, lagged three-year (1958–1960) average values of these dependent variables are used.[6]

In addition, the 1960 value of the dependent variable is introduced in all of the regressions. This variable tells us the extent of change in *relative* size of experiment stations or departments, as the case may be, across the country from 1960 to the year of the dependent variable (1966 for experiment stations and 1967 for departments). For example, if all agricultural economics departments were the same size in 1967 as in 1960, or if all grew by X number of people, this variable would "explain" all of the variation between departments in 1967. Thus, if the lagged dependent variable accounts for a large proportion of the variations explained, it is an indication that state experiment stations or departments, as the case may be, have not changed in size very much relative to each other during the 1960–67 period. And most important, if any change in relative size did take place from 1960 to 1967, we can tell whether these changes are related to differences between states in farm or nonfarm income. In addition, the equations with the lagged dependent variable are used in the next section to predict 1974 values of size of departments and 1972 total funds available to experiment stations excluding fees and sales.

All equations are estimated in linear form on cross-sectional data with

---

[6] Since we have no *a priori* knowledge of the length of lag between change in the dependent variables and the consequent effect on the independent variables, two other alternatives were tried: 1961–62 and 1963–65. For most of the equations slightly higher R^2's were obtained using the longer 1968–60 lag, although the improvement over the other lags was negligible. The decision to use the 1958–60 lag was based mainly on convenience. With the longer lag it is possible to predict further into the future, with the prediction equations of the next section, without adjusting the coefficients.

48 observations. The variables used in each equation and the results are presented in Table 3. Values in parentheses are "*t*" ratios.

10. a. Horticulture ($R+T$ personnel, 1967)	3.39	.018 (2.96)	1.35 (6.01)			.659
b. Dairy Husbandry and Industry ($R+T$ personnel, 1967)	6.53	.003 (.663)	.894 (6.26)	.064 (9.14)		.882
c. Horticulture ($R+T$ personnel, 1967)	.132	.002 (.531)	.107 (.664)	.013 (1.32)	.915 (6.35)	.939
11. a. Plant Pathology ($R+T$ personnel, 1967)	4.49	.026 (5.87)	.410 (2.46)			.628
b. Plant Pathology ($R+T$ personnel, 1967)	4.37	.042 (2.46)	.404 (2.42)	−.012 (−.969)		.636
c. Plant Pathology ($R+T$ personnel, 1967)	2.03	.012 (1.17)	.136 (1.36)	−.005 (−.745)	.836 (9.48)	.882
12. a. Poultry ($R+T$ personnel, 1967)	4.05	.006 (2.38)	.136 (1.50)			.262
b. Poultry ($R+T$ personnel, 1967)	2.63	−.003 (−1.19)	.037 (.538)	.069 (6.39)		.617
c. Poultry ($R+T$ personnel, 1967)	.268	−.003 (−1.85)	−.070 (−1.44)	.039 (4.61)	.760 (7.14)	.825
13. a. Soil Science ($R+T$ personnel, 1967)	6.36	.029 (7.66)	.069 (.481)			.656
b. Soil Science ($R+T$ personnel, 1967)	6.34	.031 (2.13)	.068 (.470)	−.002 (−.157)		.657
c. Soil Science ($R+T$ personnel, 1967)	3.43	.012 (1.04)	−.008 (−.068)	−.005 (−.589)	.892 (5.71)	.805

In view of the many factors that could be expected to influence the size of experiment stations and departments, and considering that cross section data are used, it is a little surprising that the two income variables alone account for such a large share of variation in size. This is evident in regression one, for example, where 79 percent of the variation between states in total funds available to experiment stations is explained by variation in farm and nonfarm income between states.[7]

It is also a bit surprising to see the negative coefficient, although not significant, on the farm income variable in equations 1b and 3b (the total funds available and nonfederal funds available equations with the 1960 dependent variable included). This means that from 1960 to 1966, in terms of growth, colleges of agriculture and experiment stations in highly agricultural states fell behind those in the urban-industrial states. In other words, it was somewhat a detriment for an agricultural experiment station to be located in an agricultural state during this period. The main reason, of course, is that income seems to be the important variable explaining experiment station growth, and income is highest in the urban-industrial states.[8]

---

[7] For previous work on factors influencing funds available to experiment stations, see [6].

Total and nonfederal funds available, *including* fees and sales, were used also as dependent variables (not shown in Table 3). In this case, the farm income coefficient was positive, although not significant, in equations comparable to 1b and 3b. Apparently, the experiment stations in agricultural states rely more heavily on fees and sales as a source of funds than do those in urban-industrial states.

The same general findings are obtained when rural farm population and non-farm population are used as dependent variables in place of farm and nonfarm income (not shown in table 3). In this case, rural farm population does not enter as a significant variable in the equation even when the 1960 value of the dependent variable is not included (equations comparable to 1a and 3a). The coefficients, *t* ratios, and R^2 for these equations are:

Dependent variable	Rural farm population (thousands)	*Nonfarm population (thousands)	R^2
Nonfederal funds available ($1,000)	1.07 (.722)	.683 (7.66)	.622
Total funds available ($1,000)	2.46 (1.66)	.725 (8.11)	.671

* Includes urban plus rural nonfarm population. Values in parentheses are *t* ratios.

In summary, it appears that farm income is a better predictor of nonfederal and total funds available than farm population, but neither is as good as nonfarm income. These results should comfort those who have feared a decline in support of colleges of agriculture and experiment stations because of the decline in number of farmers. The important variable seems to be number of dollars of income in the state rather than number of farmers.

With reference to the departmental equations, it is likely that higher R^2's would have been obtained had expenditure figures been available for the dependent variables instead of personnel numbers. It is reasonable to expect that the richer states pay higher faculty salaries and spend more on supporting facilities and personnel.

---

[8] For previous work on the relationship between farm and industrial states and their support of agricultural experiment stations, see [5, 1].

Some interesting contrasts come into focus with respect to the relationship between deparement size and the two types of income. Considering equation "a" in each of the departmental regressions, farm income enters as a highly significant variable for all departments except Dairy. Using size of "t" values as the criterion, Animal Husbandry, Agronomy, Soils, and Agricultural Engineering seem to exhibit the closest relationship to farm income, although the remaining departments, except Dairy, rank fairly close behind. About the same relationship holds true if we use size of coefficient as the criterion.

More diverse results are observed for the nonfarm income variable, however. The departments with the closest positive relationship to nonfarm income appear to be Horticulture, Agricultural Economics, Entomology, and Plant Pathology. It is of interest to note that two departments in the "a" series of equations bear a negative relationship to nonfarm income: Agronomy and Animal Husbandry. Moreover, for Agronomy the coefficient is significant at the .01 level.

In the "b" equations of regressions 7 and 13, the value of farm production that would seem to be closely related to the department is introduced.[9] This variable enters at the .01 significance level for Horticulture, Poultry, and Dairy. One might expect this result in view of the relatively active and cohesive producer groups representing these industries.

As might be expected, the inclusion of the 1960 value of the dependent variable in the regressions reduces both the size and significance of the coefficients on the income and related farm production variables. Also, this variable seems to exhibit relatively more strength in the experiment station regressions (1 through 3) than in the individual department regressions. This would indicate a greater change in relative size of individual departments between states during the 1960–67 period than for the entire experiment station. The greatest stability of relative size is observed in the federal funds available regression. This might be expected in view of the formula method of allocation.

To summarize the results thus far, we might rank the departments according to the strength of their relationship with income and related production in the following manner:

Closest relationship to farm income	Closest relationship to nonfarm income	Closest relationship to related production
Agronomy	Horticulture	Horticulture
Animal Husbandry	Agriculture Economics	Poultry
Soil Science	Entomology	Dairy
Agricultural Engineering	Plant Pathology	

Generally, it appears that departments with a close orientation to agriculture at the farm level bear the closest relationship to farm income, whereas those departments having a closer contact with the nonfarm sector of the economy seem to be more closely tied to nonfarm income. We might conclude, therefore, that the four disciplines in the first column will find the most favorable climate for growth in the more predominate agricultural states and that those in the second column will fare best in the urban-industrial states. Since the latter states will likely experience the most growth in income, the climate for future growth would seem to be most favorable for these four disciplines. It would appear also that the disciplines in the third column, particularly Dairy and Poultry, will become more consolidated, growing in the states with large poultry and dairy industries and declining in the others.

---

[9] The specific values used are listed at the end of Table 3.

These results imply further that the degree of support by the farm and nonfarm sectors for each discipline seems to depend on the degree of contact between the discipline and each sector. For example, nonfarm people seem to be more willing to support the disciplines they know about and have contact with, namely, the four in the second column. Although plausible, this is somewhat unfortunate because there is no reason to believe that more direct contact or relationship between a discipline and a sector also means greater benefits for that sector. The research output of the more farm oriented disciplines, Agronomy and Animal Husbandry, for example, also benefit the nonfarm sector by making it possible for agriculture to produce food more efficiently and cheaply and for labor to leave agriculture to produce other things. Because of the more remote relationship between the more farm oriented disciplines and the nonfarm sector, their future support from the nonfarm sector will depend largely on how well these disciplines inform the nonfarm public about the relationship between their research and consumer welfare. Of course, agricultural economists share this responsibility also.

Predictions for the 1970's

More specific predictions of future growth and decline of experiment stations and individual departments can be obtained by using the equations presented in Table 3. The coefficients utilized are those in the "b" equations of regressions 1, 4, 5, and 6, and the "c" equations of regressions 7 through 13. As we know, departments do not fluctuate in size a great deal; because of tenure of faculty and other institutional factors, year to year changes can at most be marginal. In view of this, it seems expedient to use the equations which incorporate the information given by the 1960 dependent variable.

In order to use the coefficient on this variable without adjustment, predictions are made into the future by the same number of years that exist from 1960 to the year of the dependent variable in Table 3: 1966, for total funds available, and 1967, for the individual departments. Thus, the predicted values obtained will be for 1972 for total funds and 1974 for the individual departments.

The length of lag for the income and farm production variables is assumed to be the same in the prediction equations as in the equations of Table 3. That is, 1967 values of these variables are used in the prediction equations. Because published data on state 1967 values of farm and nonfarm income and the various categories of farm production are not yet available, these figures are estimated by fitting a least squares trend line to the 1958-1965 observations of these variables for each state and extrapolating two years to 1967. All money values are deflated by the consumers price index, 1960 = 100, to take out the trend caused by a rising general price level.

The predicted values of 1972 total funds available and 1974 number of research and teaching personnel in each discipline were obtained for each state. However, because of space limitations these figures are aggregated into the nine USDA regions and presented in Table 4.[10] As in any other prediction, one should, of course, take these figures with "a few grains of salt." Nevertheless, it seems that they do indicate where pressure for growth or decline will be greatest.

As we might expect from the regression results obtained, those disciplines bearing the closest relationship to nonfarm income are predicted to experience the most growth, especially in the urban-industrial states. There is one exception, however. Soil science, although closely related to farm income, is among the higher growth disciplines. A possible explanation is the rapid suburbanization occurring in most states, which requires knowledge of soils and soil mechanics for construction of foundations, drainage facilities, streets and highways, etc.[11] As a result, the coefficient on the 1960 dependent variable carries relatively large weight in this equation because of the general upward trend in size of most soils departments during the 1960-1967 period. Consequently, the model comes close to being just a linear trend projection for this discipline in each state.

In the aggregate, only two disciplines—Dairy and Poultry—are predicted to decline from 1967 to 1972. It would be misleading, however, to conclude that these disciplines will decline in all states. Growth is predicted for these in states where the related industries are large and growing. By the same token, it would be misleading to conclude that the remaining disciplines, which are predicted to grow in the aggregate, will grow in every state. In fact there are only two—Agricultural Economics and Soils—for which growth is predicted in every state. Even with these,

growth in several states is predicted to be quite small. The main point to be made here is that growth in the aggregate does not mean growth in every state. The same is true, of course, for decline.

Summary

The main emphasis of this paper has been on "what is" as opposed to "what should be" with regard to the allocation of research, teaching, and extension personnel in U.S. land grant colleges and experiment stations. As expected in public institutions staffed by personnel with lengthy, specialized training periods, year to year changes come about rather slowly and are marginal in size. Although growth is the predominate characteristic at both the discipline and individual department level, we observe and can predict future decline, particularly at the departmental level within several of the disciplines.

Among the variety of factors that probably influence the size of experiment stations, state income, both farm and nonfarm, emerges as the important variable. Farm population of the state appears to a relatively minor factor affecting nonfederal and total funds available to the state's experiment station. The number of dollars of income generated in the state, not the number of farmers, seems to be the important variable determining the support of experiment stations. Moreover, in recent years, nonfarm income has become more important than farm income in explaining experiment station support. This trend will likely continue as the nonfarm sector grows relative to the farm sector of the economy.

The relationship between individual departments and farm and nonfarm income is more diverse. The departments that appear to have a more direct contact with nonfarm people bear a closer relationship to nonfarm income than the departments with a greater farm level orientation. This implies a rather unfavorable climate for future support and growth for the latter departments unless the nonfarm public becomes aware that even farm oriented research benefits consumers ultimately.

The approach of this paper and the results imply a rather deterministic view of research allocation. One could argue, of course, that administrators in colleges of agriculture and experiment stations have at least some power to determine the destiny of their institutions. Although this may be true, each has to operate within funding constraints and these constraints appear to be defined largely by the magnitude of income in the state. However, funding constraints become a greater problem only if administrators really attempt to reallocate the distribution of research, teaching, and extension in their institutions. But the stability of relative shares suggests that tradition and rule of thumb may be preferred to the more difficult process of problem-oriented decision making.

Production Economics, Farm Management, and Extension[*]

DONALD B. WILLIAMS

Perusal of the literature of agricultural economics and some exposure to the work of personnel engaged in agricultural extension suggest the need to review relationships between the disciplines of production economics, farm management, and extension. This need arises because each of the disciplines might be expected to have significant effects on the scope, methodology, and usefulness of the others. My purpose is to try to set in perspective some of the differences in viewpoint that have emerged between different participants in agricultural economics and agricultural extension. This perspective may help to point the way to release from some aspects of the new orthodoxy within agricultural economics, whic is discussed in the paper.

The Problem in its Setting

WHATEVER the scope of production economics may be, the scope and purpose of extension, I assert, differs from that of production economics because its primary purpose is educational, and it is based on a wider range of disciplines than economics alone. Production economics is one, but only one, of the basic disciplines for both farm management and agricultural extension. On the applied side, farm management extension is one, but only one, of the components of agricultural extension.

Despite this common ground, the interchange between production economics and agricultural extension has so far been largely a one-way flow of influence and information. Economists have sought to apply their principles in farm management extension. But many of the problems encountered in day-by-day extension programs have had little effect on the immediate purposefulness of production economics, although they have influenced its scope.

One is therefore led to a second assertion: there has been a breakdown in communication between personnel in the basic discipline of production economics and personnel in the applied science and art of agricultural extension. Each of these fields has been evolving at a different pace and in a different way, with different basic skills, different purposes, different per-

---

[*] This paper had its origins in a plan, initiated in 1964 by one of Professor Earl Heady's followers, to edit a volume of essays on production economics in the 1960's to be written in honor of Professor Heady. This paper was to cover the field of production economics in relation to extension, but the plan to produce the volume was not fulfilled. My thanks for comments on earlier drafts are recorded to A. C. Egbert and B. L. Lanpher and to A. Lloyd, N. Sturgess and T. MacAulay. J. Dunbar and R. L. Mighell also made helpful comments and suggestions.

DONALD B. WILLIAMS *is visiting professor of agricultural economics, University of Melbcurne, Australia.*

sonnel, and as part of the activities of different institutions—without much interaction between their mainstreams of scientific discipline and folklore.

The failure of extension and farm management to exert a more active influence on the scope and purpose of production economics has been an important feature of agricultural economics during the past twenty years. It reflects in part the persuasive nature of Earl Heady's leadership in establishing a new framework for production economics. But other influences as well have hindered the shift in focus of interest within production economics toward the experience and problems of extension. Among these has been the failure of Heady's colleagues to keep his contribution in perspective and to rise above and beyond his magnificent insight so as to realize the implications and the limitations of his new orthodoxy.

Still other important influences are the institutional arrangements under which the disciplines of economics and extension are organized in different countries [17].

From Production Economics to Extension

Production economics, if it has standing as a discipline, is comprised of principles and concepts that provide for interpretations of the economic relationships existing among resources used in individual firms. Once defined, these principles and concepts should find universal application; if they fail to do so, production economics loses claim to status as a separate discipline. Unfortunately, this failure often has occurred whenever production economics has assumed that the institutional structure of farming —not to mention the human nature of farmers—is a neutral umbrella which can be added as a superstructure to the model or principles without becoming an integral part of them. Thus, it would appear that production economics so far has not formalized a set of principles that takes account of differences in motives, behavior, and institutions between different countries, or different regions within countries.

Farm management, by contrast, is an applied discipline that finds its identity in relation to the whole set of established social institutions and to the structure of farming in a given country. It is designed to develop principles that provide understanding of agricultural practice and managerial performance, as an aid to individual farm enterprises and as a basis for agricultural policy. It links the disciplines of production economics and agricultural extension, though it does other things as well.

When one turns to extension, the difficulties of identifying a separate discipline are greater. This is so because an element of art and intuition is involved in educational processes and because the processes of education within societies are founded on some comprehension of a wide range of social and individual behavioral disciplines. Furthermore, the form and scope of extension differs greatly between countries. Even more than farm management, extension takes its form from the institutions of which it is a part and from the social traditions which mold the attitude towards education and economic or social change of people in the culture concerned. For example, the emphasis given to different sectors of the rural community—commercial farms, subsistence farms, rural youth, farm wives—varies according to the degree of association between extension and government development programs, as well as the scope of other adult education services.

Experience over the years in the United States has shown that extension has been a significant component of the armory used to tackle rural problems [14]. Farm management has tended to maintain close association with cooperative extension service programs, and the links between these two have been a feature of the Cooperative Extension Service from its earliest days, especially during the last 35 years.

In the United States, the farm management orientation in extension has placed emphasis on decision-making. But, somewhat ironically, the problems involved in decision-making lead far beyond the scope of production economics, at least beyond its scope as it has so far developed as a professional discipline. Ruttan [15, p. 1494] spells out this point clearly when he discusses the implications of accepting production economics as "simply one of the applied behavioral, social, biological, and physical science disciplines upon which farm management is based. . . ."

Changes in progress within the Cooperative Extension Service have far-reaching and fundamental implications for the land-grant colleges, which infused the educational component into extension. The implicit but emerging conflict between the Cooperative Extension Service as a government agency and its role as an educational organization must be expected to have repercussions on the scope of farm management extension. Pressures are growing for extension to become less concerned with the welfare of farmers *per se* and more concerned with the relations of farm industries to productivity of the economy as a whole. Increasing emphasis is placed on specific audience groups such as rural youth, commercial farmers, or part-time farmers, as well as urban groups and marketing firms.

Despite these important changes, the United States extension scene still reflects its well-entrenched management component. Farm management has been an established discipline in land-grant colleges for many years, with its extension and research specialists. In a dynamic society where changes in occupations and land use are in progress—both are necessary components of economic growth—farm management principles can help to interpret changes and point to the feasibility of change as a basis for extension programs.

Recent reviews by Camm [4], Davies [7], and Giles [8] indicate the difficulties being met in bridging the gap in the United Kingdom between different disciplines and between research and advisory activities. Davies reports that too much emphasis has been placed on descriptive analysis and stresses the need to define problems precisely, in order to move into the problem-solving stage. This requires closer co-operation with the natural sciences, not only by research workers but by advisers, particularly at the initial planning stages when problems are being defined. The research results eventually obtained can then be comprehensible to both extension agent and farmer.

Camm acknowledges that most of the sophisticated and complicated farm management research techniques are "beyond the grasp of advisers and unintelligible to farmers" [4, p. 27]. He suggests the gap between theory and practice is such that research in communications, in day-to-day farm management, and in managerial capacity would help to raise the efficiency of farming. In the communications field, he outlines the need for more effective two-way communication between the farmer and the adviser, and between advisers and research workers.

Giles, writing from the viewpoint of a farm management liaison officer, mentions the failure to achieve widespread understanding among U.K. farmers of even the simplest economic concepts. In part this arises from a tendency by agricultural economists to write "with one eye on the industry we hope to influence and one on professional reputation" [8, p. 36].

For many years, the simple principles underlying the economic structure of farm firms, input-output relations, or opportunity costs have found application in farm management. But, as Butcher [3, p. 1476] has suggested, "It is the principles, not the precision, of production economics that have proven most useful in these applications." In any case, partly because of the problem of language and the inability of extension personnel to cope with new concepts, it is not easy to point to new empirical research findings or even to new principles contributed by production economists that show promise of, or have activated, important day-by-day application in farm management extension programs. Perhaps it will be ever thus. If so, there are significant implications for both farm management and agricultural extension.

For example, we might stop worrying about the fact that production economists are not practical and let them go their way, exploring as and where they will. To do so might be feasible, at least here in Australia, if two conditions were met. First, farm management and agricultural extension personnel would need to be of high caliber and well trained, capable of making their own gleanings and interpretations of the intellectual activities of production economists. Second, and equally important, production economists would have to "play it fair" in terms of competition for status and for the financial support attracted by this status.

Since this is too much to ask (though I do so later), we are tempted—

or even forced—to turn aside from this unreal world; and like Kelso [12], we continue to worry about the low scientific predictability of agricultural economics. Yet we should realize that this implicitly demands that we do not accept a low direct payoff in the applied extension field from work in production economics.

Implications of Production Economics Methodology

In 1963, as part of his analysis of changes in the United States since 1952, Glenn Johnson identified the widening gap between production economics and extension. He wrote:

> The proportionate use of farm management research by extension workers has decreased as its production economics orientation has increased. This is associated with:
>
> (a) decreased relevance in practical farm management problem situations of much of the current production economics research in farm management; and
>
> (b) the failure to increase competence with respect to production economics as rapidly among extension as among research farm management workers . . .
>
> 'Production economics' oriented farm management workers have either largely ignored or been largely ignored by the editors of the Journal of Farm Managers and Rural Appraisers, whose supporting association and membership have maintained a keen interest in the practical problems of farmers. [10, p. 17].

Production economics has made a major contribution in the field of public policy as a guide to the interpretation of supply responses by different industries and from different regions. This role, which first found its full expression in the United States adjustment programs of the 1930's, has continued to be the heart of applied production economics over the years. Adjustment problems may arise from a market collapse, as in the United States in the 1930's; from war, as in the United Kingdom in the 1940's; from pressure on balance of payments, as in Australia in the early 1950's; or from changes in the rural sector through new trade arrangements and economic growth centered in the industrial sector, as in Europe in the 1960's.

In developed countries where production economics has flourished, there has been much emphasis in recent years on economic growth and on the effects of various protection and price support programs. This has drawn attention away from the institutional structure of rural industries, away from imperfections in markets for factors of production, and away from the analysis of the significance of differences in the structure of farming and the technical and commercial services associated with rural industries. Yet these are the very aspects of farming that extension programs need to take into account, as specialist consultants from developed countries have learned to their cost when called upon to assist in development programs of undeveloped countries.

This shift of emphasis towards problems of economic growth and the relations of the rural sector to growth of the whole economy once again seems to have enabled production economics to turn aside from the critical problems of individual motivation and preferences that underly behavior and might provide a more formal basic discipline for extension personnel. One would be foolish to deny the importance of the new emphasis on economic growth; but one must also point out that when the time comes to bring into practice—within extension programs—some of the policies which emerge from the macro-analyses, much more knowledge of the problems and behavior of individual farms and of farmers will be needed. Production economics has not yet provided an adequate framework to interpret and apply this knowledge.

Much of the "prideful development" in agricultural economics described by Kelso bears on the contributions of production economics to aggregate problems and to methodology, rather than to improved understanding of individual farms. Kelso considers that:

> Most of the remarkable current developments in agricultural economics equip us only to be more exact, more positive, more quantitative, more complex in our rationalistic analysis of hypothetical, simplified, imaginary systems from which man—as a partly irrational, unpredictable, emotional animal—is banished, to be replaced by the lightening calculator in human form. [12, p. 5].

The new methodology has provided means of identifying relations within specified systems, even if the variables used are not always ideal as a measure of the real world situation; when it comes to the real world, we cannot even be sure that the questions posed and answers provided by economists, restrained as they must be by the limits of scope and of definition implicit in their models, are the important questions and answers. The models do not imply the important questions because they exclude important variables, such as those relating to behavior and to institutions —often because these can't (yet?) be quantified by traditional mathematical methods. In Kaplan's phrase, much effort is vitiated by the principle of "the drunkard's search" [11, p. 11]. The drunkard searches under a street lamp for his house key which he had dropped some distance away. Asked why he doesn't look where he had dropped it, he explains, "It's lighter here."

As economic growth proceeds apace, the institutions associated with farming—land tenure, contract services, credit, and marketing arrangements—may also change rapidly. Farm management workers and extension officers are involved in and participate in these changes. The production economist fails to serve their needs if he conducts his analysis within a framework that abstracts from the relations between institutional factors and the best allocation of resources.

It makes little difference whether the resource allocation be best in terms of the welfare of the rural sector or of economic growth of the whole economy. In either case the analysis is incomplete unless the production economist takes account of the existing institutional restraints and considers how growth or change or new policies may influence them; he must also weigh how farmers will respond to changes in factor prices within the evolving institutions that also may be a part of economic growth. Superimpose on all this the effects of extension education on the farmer's technical efficiency, on his use of institutions, and on the values and preferences that underly his behavior patterns—and some comprehension can be obtained of the complex interaction between production economics and extension education.

None of this is to deny that much of the information provided by production economists is helpful to the farmer. So, too, is the analytical framework which embraces diminishing returns, opportunity costs, rates of substitution between inputs and between outputs, and so on. But, from the extension educationists' viewpoint, there is need to interpret these principles to meet the circumstances of farmers as individuals or as groups. Moreover, extension specialists have a responsibility to communicate effectively about the nature of problems encountered in extension and agricultural practice and to specify the parameters needed for the improvement of farmers' decisions. It is in the interpretative phase that communication between extension and production economics has so far frequently been found lacking—not so often because production economics is wrong within its own limits, but because its limits are inadequate and because its interests are elsewhere. As a result, it provides only a partial explanation of the economic aspects of human organization and activity and says even less about the social and wider behavioral aspects.

Production economics provides an internally consistent logic by which it defines the systems and conditions for optimum economic use of resources. For those who are fond of such exercises, there is intellectual satisfaction and delight in the establishment of models and the successive release of restraints so as to analyze relations and interactions in ways that purport to give some understanding of the real world.

However, when assessing the scope and adequacy of the models, a fundamental methodological problem is involved. When models are used to interpret real situations, the scientific discipline, providing for comprehension of relations within the model, gives way to interpretation and insight which breaks away from the formal guidelines of scientific method. It is about the methodological implications of this process of interpretation and insight that we are so ignorant. Conklin saw this clearly when he wrote, in 1960:

> On the human side also, we usually ignore factors that determine how our recommendations will be received . . . [6, p. 1480].

And again:

> Some claim that the job of tailoring recommendations to men and institutions is the job of extension personnel. This is the way, of course, in which we have avoided facing up to the limitations of the image of the world we have been using. Anything that does not fit the deterministic mechanical mould is pushed off into extension, or policy, or some other fuzzy area where the workers do not have exalted scientific ambitions. [6, p. 1481].

To me, it is somewhat unsatisfying to use these models as a starting point, successively releasing restraints and adding 'real world' assumptions in order to achieve some comprehension of this real world. What if the restraints interact with one another? Starting from the other end, if some brave omniscient could conceive of the many human and institutional interactions and relations in the real world and then proceed to simplify these by removing variables one by one so as gradually to make them more akin to our models, would he meet in the middle with those present-day production economists who move away from their models by the successive release of restraints?

I suspect that human activity and systems of organizations are not yet amenable to so-called scientific analysis based on quantitative analytics alone, if understanding rather than predictive power is the purpose of our inquiry. While predictive power is one of the legitimate purposes of scientific inquiry, one must strive for a higher order of understanding as a basis for the educational programs to which extension officers devote their professional efforts.

Perhaps this is an underlying cause of problems referred to by Kiehl, when he writes of the younger workers in extension who are forced into a "research Ph.D. mold" and are thereby led to overlook the tremendous educational opportunity with lay people.

> Part of the high attrition among younger workers, no doubt, is due to the inherent result of present Ph.D. programs tending to engender personal aggrandizement in new-found research of theoretical skills. Somehow some have lost their 'educational touch' and embarked on a personal program of emphasizing their newly acquired competence. [13, p. 1456].

In the meantime, those concerned with practical problems need courage and support to move beyond the evanescent prevailing concepts of scientific method. It is part of the history of agricultural economics that such courage and support has not always been evident, and so an inbuilt orientation has evolved in our profession towards "scientific" production economics rather than towards "unscientific" farm management and extension. Using concepts to solve problems, too often we have become so interested in concepts that we have lost sight of the problems.

In the United States—and in Australia too—the gap between production economics and farm management, which showed such promising signs of narrowing a decade ago, has now widened. Production economics has turned more and more to research methodology and policy implications, while farm management extension has remained as empirical as ever, face-lifted though it has been by some help from computers to do the arithmetic involved.

Among production economists—and here I have in mind particularly those of the United States, United Kingdom, and Australia—the growing emphasis on uncertainty and on inter-disciplinary approaches to input-output analyses on the biological side, and to decision-making and behavioral studies on the social sciences side, has all been well-meaning enough. But these new efforts have not yet paid off in terms of their influences upon practitioners of either extension or farm management.

Nor have there been great advances within farm management. Can we record significant changes in knowledge or concepts within problem areas, such as classifying farms on a more meaningful economic basis, getting access to farm data, interpreting farm costs, analyzing different components of farm income, and measuring management inputs, or in the problems of spreading capital costs over time?

Progress has been slow in devising new concepts within production economics that have an application in farm management practice. The use of well-worn farm management principles—mainly diminishing returns and opportunity costs—is proceeding apace, simply because of the need to solve problems that press for attention. Yet there is also enough difference between and within countries to enable the scope and technique of farm management extension to gain from efforts to apply more widely what is already known, however intellectually unsatisfying this may be to some.

An important comment is made by Ruttan [15, p. 1492], when assessing the significance in the late 1940's and early 1950's of the "intellectual challenge associated with the developments in economic theory and quantitative method . . ." He proceeds to state what surely is a counsel of despair:

> I do not expect to see this challenge duplicated in the immediate future. Indeed, I would argue that economic theory and the related quantitative disciplines are experiencing a period of consolidation and refinement rather than a new burst of insight at the present time.

Far less than meeting the challenge, this statement fails even to acknowledge it, at least as a component of "economic theory and the related quantitative disciplines." What was that about a drunkard's search?

My own somewhat heretic belief is that constant empirical busyness, as well as efforts toward a wider application to new extension problems and situations founded on but not limited by known economic principles, will create a situation in which original minds will gain insights that may well be lost to others concerned with more abstract relations and principles. I have a suspicion that the Iowaites do this too, but won't admit it (much less publish it), and feel bound to pay homage to a methodology that stresses the quantitative analytical deductive method. Whatever may be the merit of their economics, one is compelled to admire their gamesmanship, which so often appears to impose intellectual obsolescence on their blood brothers in farm management extension. Conform or be damned, they say, and we'll be damned if we do.

Orthodoxy and Dissent

How ironic it is, here, now, in 1968, that so much of the new orthodoxy, which for two decades has linked farm management and production economics, leads us to see more clearly the confined scope of production economics and the need to rise above and beyond the constraints exercised by this discipline, if problems of the real world are to be tackled.

In retrospect, one may hope that the 1960's will be seen as the period when the influence of humanism in the sciences, including economics, matured. Heady's great contribution has been to provide a model that is brilliantly conceived but contains the seeds of its own destruction, because it abstracts from problems of human behavior and institutions and concentrates on resources as such.

It is not that anyone else has done better, nor that Heady has not been as much concerned with investment in human resources and economic development as the next man. But his contributions to methodology have tended to abstract from problems of behavior; and his subsequent interest in problems of economic development seems sometimes to depart from some of the restrictions of his own models and methods, which have been his heritage to the profession of agricultural economics. In problems of macro-theory, there is little of the formal elegance of his micro-economic models. This is at least circumstantial evidence that in the world at large something more is needed as an aid to the interpretation of and advice about individual farm problems.

Yet in 1952 Earl Heady, in Glenn Johnson's words, articulated in a remarkably accurate way the then prevalent mood of the members of the profession of agricultural economics [10, p. 16]. Indeed, this great articulation in the 1950's by its nature has led us to see more clearly the need for another such intellect to address himself to the new situation in 1968 and reveal how the restraints implicit in our accepted principles and beliefs have limited the form and the application of agricultural economics.

It is for the profession of agricultural economics to encourage the contributions that will render our own made-in-the-1950's kit of methodological tools intellectually obsolete. If, as Kelso argues, agricultural economics is indeed an art, then we should take account of the view of an historian of art as to the ways by which schools of art emerge and disintegrate. Collingwood says:

> To the historian accustomed to studying the growth of scientific or philosophical knowledge, the history of art presents a painful and disquieting spectacle, for it seems normally to proceed not forwards but backwards. In science and philosophy successive workers in the same field produce, if they work ordinarily well, an advance; and a retrograde movement always implies some breach of continuity. But in art, a school once established normally deteriorates as it goes on. It achieves perfection in its kind with a startling burst of energy, a gesture too quick for the historian's eye to follow. He can never explain such a movement or tell us how exactly it happened. But once it is achieved, there is the melancholy certainty of decline. The grasped perfection does not educate and purify the taste of posterity; it debauches it. [5, p. 11].

How much we need, as Schultz observes, a dialogue similar to that of a generation ago between farm management and agricultural economics to "bring the agricultural sector back into focus and to make our studies of the farm-firm more relevant" [16, p. 1010]. The new dialogue needs to be expressed in terms of economics and its application in farm management and extension, and to explore how, in this application, economics changes its form.

Such a dialogue also needs to pursue what Boulding, in his 1957 paper on institutional economics, has so aptly called "the general sociology of dissent" [2, p. 2]. Boulding identified himself with some of the discontent with orthodox economics expressed by the institutionalists. He wondered why in many different fields such as economics, religion, art, philosophy—indeed in almost every aspect of human life and thought—certain viewpoints or developments established themselves as orthodox or "mainstreams"; and why dissenters, with their pugnacity, shrillness, and asceticism, perceive themselves as dissenters not belonging to a mainstream of orthodoxy.

Boulding acknowledges "a somewhat despairing concern for dynamics in theory," and "a very strong concern for integration in the social sciences and for bringing contributions from psychology, sociology and the biological sciences into the construction of better theories of individual behavior and social change"; he also expresses "a strong (if skeptical) interest and sympathy with empirical methods" [2, p. 12]. Ayres, in commenting on Boulding's paper, identifies the dissent of the institutionalists as centering on the role of the market, which at most only gives effect to the prevailing institutions—the organizational structure of society that is the "real determinant of whatever allocation occurs in any society" [2, p. 26]. The institutionalists further argued the importance of the state of the industrial arts, which determines the relative scarcity or plentifulness of resources. All this seems to have a particular significance to the present state of agricultural economics, and especially to production economics.

Hildreth [9, p. 839] has made an attempt to set out hypotheses concerning the causes of tension between research and extension workers within agricultural economics. He suggests, in three alternative hypotheses, that tension is caused: by difference in orientation to variables of time and depth of analysis; by the different methods and supporting disciplines used by the two groups; or by different scholarly social circles of research and extension workers. Hildreth presents these hypotheses "to arouse discussion and thought which might lead to their evaluation," and recognizes that the precise testing of these hypotheses would be a major task. His approach implies that tensions of this kind are harmful ('disturbing') and that disparaging statements reflecting these tensions "tend to destroy self-esteem and mutual respect between research and extension workers, which are vital for the productivity of the profession." This statement is, indeed, yet another hypothesis which may need to be tested, for one might alternatively argue that from tensions of this kind, hard to bear though they may be, come some of the original breakthroughs in understanding within our profession of agricultural economics.

Another hypothesis worthy of test is that much of the responsibility for the default underlying the breakdown in communications between production economics and extension must be laid at the door of the extension profession itself. This is to say, until extension personnel communicate their needs (gaps in information; problems of interpretation of research findings) more explicitly and exert an influence on production economics, and until more resources are attracted to build up an analytical framework as a basis for the empirical methods now used in extension, many of our problems will persist.

Glenn Johnson has astutely argued the importance of the philosophical attitudes underlying the discipline of farm management; but his emphasis has retained an orientation towards research methodology, rather than the related problems of interpretation and application of research results in extension programs. In an interesting reaction to Johnson's analysis, Baker [1, p. 154] observes: "However, there is a sense of frustration too in Professor Johnson's analysis. The partitioning of the investigational field into positive and normative becomes most nebulous. More important, his conclusions lack definition on prescriptive proposals for research investigators. Instead, we are exhorted to be more useful." Baker then suggests

[1, p. 155] an ". . . alternative division of the investigational field. . . . Distinctions made by reference to models or data are at best ambiguous and at worst misleading. The distinction useful in research lies in the orientation of the whole research process, with special emphasis on perception of the problem and formulation of it for research, not in the specific model used in the research."

We need to expand these confrontations, starting from the basic philosophical foundations of economics, to explore production economics, farm management and agricultural extension. At each step in this exploration the purpose would be to identify how the use of models, the role of the human mind in developing propositions while also being the observer, and the changing status of human society as the subject for study, each exerts an influence on the information and attitudes contained in the ultimate end-point of extension education. That is, let us show how these successive steps all influence the nature and scope of information conveyed to farmers, and how they influence the technique of extension. If all this is old-hat to production economists, philosophers, or social scientists, it is surely time that one of them took pains to express the current state of each discipline in a form which reveals its implications to practitioners of other subjects and to pragmatists who have to solve problems in human welfare.

Such an exercise, directed towards a pragmatic purpose, may well reveal new contributions which the applied social sciences can make to scientific method itself.

In the real world, educational work with farmers has its place as well as quantitative analytics, and workers in neither field should have sole claim to orthodoxy within the profession of agricultural economics nor refrain from the shrillness, the pugnacity and the asceticism of dissent.

An Aggregate Model of Agriculture—Empirical Estimates and Some Policy Implications*

ALVIN C. EGBERT

The qualitative nature of the U.S. national farm price and income dilemma has long been generally but rather vaguely known. Contemporary econometric analysis can identify more precisely the magnitudes and interrelations that compose and surround this perplexing dilemma. This article undertakes to go beyond the established approach of measuring supply and demand price elasticities to the equally important and perhaps more productive identification and measurement of the relevant supply and demand shifters. By projecting magnitudes to 1985, long-run policy implications of prospective changes can be examined with greater acuity.

THE farm price and income dilemma has been around a long time. Except for unusual periods such as wartime, agricultural output tends to race ahead of commercial market outlets. As a result, without special programs, prices of farm products deteriorate over time relative to prices in other sectors of the economy. And farmers' low position on the income ladder does not improve much in spite of and, to a degree, because of great advances in productivity. The nature of this income dilemma, in a qualitative sense, is well known and has been well documented. Its quantitative nature is still quite vague. The disagreements concerning the production-consumption gap in agriculture and the magnitudes of supply and demand price elasticities for agricultural products are evidence of this vagueness.

The primary objective of this paper is to throw some additional empirical light on the price and income problem through the use of contemporary econometric techniques. In the first part, we present a simple step-by-step development of the methodology. Next we show that supply and demand price elasticities are only part of the explanation of the farm income dilemma. This conclusion is not new. See, for example, Cochrane [1]. Others, too, have been aware of the total problem [3], [4], [5], [6]. Yet, much of the empirical work has focused on measurement of supply and demand price elasticities. An equally important and perhaps more productive activity may be the identification and measurement of the relevant supply and demand shifters. In this article, we attempt to do both.

In the final section, some of the longer-run policy implications that result from the analysis are presented, assuming, of course, that the model has a large degree of validity.

---

* I want to acknowledge the comments and suggestions of J. Dawson Ahalt and Fred Abel, which contributed to the present version of the paper. The views and conclusions presented in this article are mine and are not to be attributed to the U.S. Department of Agriculture.

ALVIN C. EGBERT *is an economist with the International Bank of Reconstruction and Development, Washington, D.C. (formerly with the U.S. Department of Agriculture).*

The long-run implications depend on relative rates of change in total supply and total demand for agricultural products, including stocks, imports, and exports. These changes in turn rest on technological developments, general economic expansion, population growth, changes in factor and product prices, agricultural policy, and so forth. In order to look at policy implications, projections to 1985 are made, based on assumed changes and trends in major factors that affect growth or decay in the domestic supply and demand for agricultural products. The effects of alternative growths in exports also are evaluated.

Conceptualizing the Supply and Demand Structure of Agriculture

The general model:

$$Ay_t + B_1y_{t-1} + \cdots + B_iy_{t-i} + \cdots + B_ny_{t+n} + Cz_t = e_t \qquad (1)$$

Definitions:

A = a matrix of coefficients related to current endogenous variables
B_i = a matrix of coefficients related to endogenous variables lagged i periods
C = a matrix of coefficients related to current exogenous variables
y_t = a vector of current endogenous variables
y_{t-i} = a vector of endogenous variables lagged i periods
z_i = a vector of current exogenous variables
e_i = a vector of errors

The model as specified by (1) is quite general and can include any number of products with *supply* and *demand equations* for each, identities for market clearing conditions, definitional equations, and so forth. This system implies that the endogenous variables are either recursively or simultaneously related, or both.

The model (1) allows for a very large but finite number of commodities. However, to keep the analysis relatively simple so that the policy implications are clear, all agricultural commodities are aggregated to one product in this application of the model. Feed and seed are netted out of this aggregate because they are consumed within the agricultural sector.

A priori structure

Domestic Supply.—From a pure theory viewpoint, supply of a product is expected to be functionally related to the price of the product, prices of variable inputs, the level of fixed factors available for production, and the level of technology. Consequently, *a priori*, the supply function was assumed to take this general form:

$$QP_t = f(P_t, \cdots, P_{t-i}, \cdots, P_{t-n}; \cdots, PP_{t-i}, \cdots, PP_{t-n}; WI_t, L_t, T_t) \qquad (2)$$

where

QP_t = total domestic agricultural output except feed and seeds (value aggregate, 1957–59 farm prices), in year t

P_{t-i} = index of prices (1910–14 = 100) received by farmers for all products except feeds, lagged i periods

PP_{t-i} = index of prices paid (1910–14 = 100) by farmers for items used in production, lagged i periods

WI_t = index of weather

L_t = total cropland used for crops

T_t = time, a proxy for technological change, 1949 = 49

WI_t, PP_{t-i}, L_t and T are assumed to be exogenous or predetermined.

Domestic demand for consumption.— Similarly, *a priori* domestic demand was assumed to be functionally related to price at the farm; the marketing margin, prices of all nonfood commodities, total disposable income, and other non-identified variables related to time. Symbolically, the general demand specification is:

$$QC_t = f(P_t, \cdots, P_{t-i}, \cdots, P_{t-n}; FR_t, \cdots, FR_{t-i}, \cdots, FR_{t-n}; NF_t, I_t, T_t) \quad (3)$$

where

QC_t = total domestic consumption of agricultural products (value aggregate, 1957–59 farm prices) in year t

P_{t-i} = same as above

FR_{t-i} = index of farm retail price spread (1957–59 = 100), lagged i periods

NF_t = consumer price index for all products except food

I_t = total U. S. disposable income

T_t = time, a proxy for changing tastes and other factors affecting consumption that are related to time but are not specified

FR_{t-i}, NF_t, I_t and T_t are assumed to be exogenous or predetermined.

Domestic demand for stocks.—In addition to domestic demand for consumption, there is also domestic demand for stocks. In a pure market economy, the demand for carryover stocks is expected to be a function of stocks at the beginning of the period, current market prices, expected prices, and perhaps a general shift variable such as the level of consumption. However, the major part of agricultural stocks are commodities under price support programs. Hence, stocks are usually accumulated when current market prices are below support prices and reduced when market prices are above support levels. For these reasons, the *a priori* stock demand function was specified as:

$$ES_t = f(P_t, PS_t, ES_{t-1}, QC_t) \quad (4)$$

where

P_t = the same as above

PS_t = an index of support prices for all price supported commodities
ES_t = ending or carryover stocks (value aggregate, 1957–59 farm prices)
QC_t = same as above

Trade.—Imports and exports are the two other quantities that have a significant effect on production, consumption, and prices in the agricultural sector. In fact, these variables complete the supply-demand balance identity which follows:

$$ES_{t-1} + QP_t + IM_t = QC_t + EX + ES_t \tag{5}$$

where

IM_t = imports in year t
EX = exports
ES_{t-1}, QP_t, QC_t and ES = the same as above

Imports represent an additional source of agricultural supply, and exports represent another component of the demand for agricultural products. Conceptually, *a priori* functions could be specified for these variables. However, due to lack of data on foreign prices and markets, these two quantities were assumed to be exogenous, i.e., determined independent of the domestic market.

Only post World War II data, 1947 through 1966, were used in the analysis. These data are given in the appendix, together with an explanation of their sources and derivation.

Methodology and Interpretation of the Empirical Model

Structural equations

Because the model involves variables whose values in any one year are simultaneously determined, the three-stage least-squares technique was used to estimate the structural parameters. For purposes of comparison, the parameters for the structural equations were also estimated by the ordinary least-squares method.

As is usually the case in empirical analysis, some of the above *a priori* specifications were abandoned; some variables were dropped and others added.

Generally, variables were dropped from the equations if coefficients were not statistically significant. All variables, except price in the supply and consumption demand equations, are significantly different from zero at the 5 percent probability level or less. Price was retained in the supply and consumption demand equations, even though the t ratios are less than those of the 5 percent probability level, because (1) the signs are theoretically correct and (2) price is needed to retain a semblance of an economic structure.

While the estimated price coefficients lack precision, derived elasticities are small even when two or three standard errors are added or subtracted; thus, they are consistent with other empirical estimates.

Other variables were added to the equations mainly after analyzing the predictability of the reduced-form equations. For example, analysis showed that there were large differences between actual and predicted stocks when the weather index was above and below average. Further reflection on this fact led to the conclusion that weather should be included in the stock equation. In the data framework used, stocks are measured at the end of the calendar year. Thus, if a huge crop is harvested in the fall, stocks are not likely to be down to a normal level by the end of the year even though prices are very low. In other words, a large crop flows through the distribution channels throughout the year at a more or less normal seasonal pattern.

The final form of the structural model is presented in Table 1. Variables in the final equations not yet identified are:

IP = income per capita

POP = population, total

The negative coefficient for nonfood prices may be explained by the large expenditures by consumers for nonfoods relative to food products. This follows the theoretical case in which the income effect of a change in the price of a product is greater than the substitution effect.

The "best" empirical model turned out to be one that was simultaneous in terms of price, i.e., there are no lagged responses to price in the structural equations as shown in the *a priori* specifications. Theoretically, we would expect some lags in adjustments to price changes. However, sector lags apparently "wash out" in the aggregates. But the same general conclusions with respect to long-run changes would result if measured adjustments were not instantaneous, but made with some lag, as lesser aggregate analyses for livestock have shown (see [2]). Time aggregation, too, can obscure lags in adjustments. For some crop and livestock products—poultry, eggs and vegetables, for example—the lag between price changes and output changes is probably less than a year.

In most cases, the parameters estimated by the three-stage and ordinary least-squares have the same relative magnitudes and the same signs. The reason for this similarity needs further exploration. All signs are consistent with conventional theory. The estimated coefficients of the supply equations differ most. As expected, the R^2's of the ordinary least-squares equations are equal to or greater than those for the three-stage estimates. Of course, the R^2's for both sets are based on the assumption that prices are known or exogenous, which indeed they are not. Thus, in the context of the specified model R^2's for the structural equations are irrelevant.

Elasticities were derived from the slope coefficients, using averages for

Table 1. Estimated structural equations

1	1	.0065 (.0046)	0 =	8.8555	0	0	0	0	0	−.2236 (.0446)	.0040 (.0011)	.2039 (.0391)	0	0	0	.990
0	0	.0377 (.0077)	1 =	10.1122	.5754 (.1462)	.1978 (.0755)	0	0	.1597 (.0269)	0	0	0	.0466 (.0126)	0	0	.994
−1	1	0	1 = 0		1	0	0	0	0	0	0	0	0	1	−1	—

[a] Numbers in parentheses are standard errors of the coefficients and number in brackets are the partial elasticities computed at mean of the values for 1964–66.

[b] Annual percentage change computed at mean of endogenous variable, i.e.,

$$\frac{\frac{\gamma y_i}{\gamma T}}{y_i} \times 100.$$

[c] Derived from the residuals.

1964–66 (Table 1). Price elasticities for both supply (.27) and consumption demand (.06) appear to be in line with current thinking; both are very inelastic.

Reduced-form equations

In order to obtain a measure of "predictability" of the structural model, it is necessary to derive reduced-form equations. This derivation involves the following simple matrix equation manipulation:

$$\begin{aligned} Ay_t + By_{t-1} + Cz_t &= 0 \\ Ay_t &= -By_{t-1} - Cz_t \\ Y_t &= A^{-1}(-B)y_{t-1} + A^{-1}(-C)z_t \end{aligned}$$

Thus, the matrix of coefficients of the exogenous variables (C) is premultiplied by the inverse (A^{-1}) of the coefficient matrix of the endogenous variables. Consequently, the coefficients of the reduced-form or the predictive equations are complex functions of the coefficients of both the endogenous and the exogenous variables.

The reduced-form equations derived from the three-stage least-squares structural equations are presented in Table 2. Again, ordinary least-squares estimates of the reduced-form equations are presented for comparison.[1] While the ordinary least-squares estimates of the reduced-form equations are consistent, they are less efficient asymptotically than three-stage least-squares estimates [7, p. 365]. This is true because more restrictions are placed on the estimates via the specifications of the structural equations.

Both estimates of the reduced-form equations are quite similar. However, in several instances the signs are inconsistent with economic logic and theory. The derived structural equations have fewer inconsistent coefficients than the directly estimated equations. This results because the structural equations have the correct signs. However, to be completely consistent, the coefficients also need to be of a certain magnitude. For example, the weather variable appears both in the supply equation and in the stock equation. Because the coefficient for weather in the stock equation is greater than the one in the supply equation, favorable weather increases stocks more than output. Consequently, price increases. This does not appear to be reasonable and is certainly a limitation of the model as it stands. Use of fiscal year data might correct this defect. The inconsistent signs in the directly estimated reduced-form equations result, at least in part, from multicollinearity. However, the estimating precision, R^2, is greater for these directly estimated equations.

---

[1] The reduced-form, ordinary least-squares equations were not derived from the ordinary least-squares structural equations, but each equation was fit independently in reduced form.

[a] Numbers in brackets are "total" elasticities computed at the mean of the values for 1964–66.
[b] Derived from the residuals.
[c] Theoretically, the sign is wrong.

Note that the coefficients of exogenous variables in the reduced-form equations are usually less than the comparable coefficients in the structural equation. For example, a one-unit increase in the use of land is estimated to increase output by .09 unit in the structural equations, but by only .05 unit in reduced-form equations. This difference is explained by the fact that the coefficient for land in the reduced-form equation is a function of not only the direct effect of the production equation, but also all price coefficients of the other structural equations, namely .0076 and .0367.

Elasticities for the reduced-form equations are also presented in Table 2.[2] As indicated by these elasticities, time, a proxy for technology, plays a significant part in expanding agricultural output over time. This result is no surprise. As indicated in Table 2, with no change in the other variables, output (in terms of 1964–66 levels) increases about 2.1 percent; consumption increases .25 percent; prices fall almost 4 percent; and stocks increase about 3 percent.

Population, as indicated and as is well known, is the most important shifter on the demand side. However, an elasticity of 1.06 is somewhat hard to explain, except possibly by the increasing proportion of young people in the total population. However, given the probable error, it is sufficiently close to unity, the usually assumed value, to be credible. Per capita income is an important demand shifter, too, especially in recent years of high income growth.

The elasticities in Table 2 demonstrate that price elasticities of supply and demand are only one facet of the farm output and income dilemma. Supply and demand shifters and their relative rates of change are extremely important in determining output, price, and income levels in agriculture over time. And, whether the long- and short-run price elasticity of supply or demand is X or Y percent looms large only in explaining short-term price fluctuations.

The relationship between the estimated values and the actual values of the endogenous variables are shown in Figures 1-A, 1-B, 1-C, and 1-D. The estimated values are based on historical values of the exogenous variables and sequentially estimated values of the lagged endogenous variable, ES_{-1}. In other words, the historical estimates were made in a year-to-year sequence. For example, ES_{-1} for 1947 (actual ES for 1946), together with the exogenous variables for 1947, was used to estimate $\widehat{QP}$, $\widehat{QC}$, $\widehat{P}$ and $\widehat{ES}$ for 1947. Then $\widehat{ES}$ for 1947, together with the exogenous variables for 1948, was used to estimate the endogenous variables for 1948, and so forth. As can be seen, the estimates of the endogenous variables "track" the actual values quite well. This was indicated by the R^2's. However, these coefficients are

---

[2] Note that these elasticities are "total" elasticities; that is, they reflect the net effect of the exogenous variable on the endogenous variable after price changes are accounted for (see table 1).

not very precise indicators of how well the turning points are predicted. Graphics adds this information.

The Future and Policy Implications

In the span of little over a year, the general attitude has swung from "agricultural output must be turned loose or millions around the world will starve" to "lets keep output under control or farm prices will fall to disastrous levels." What is a realistic attitude? Do we still have a production-consumption gap in agriculture?

The model was used to throw some additional light on this question. While such an aggregative model can not give precise irrevocable answers, it hopefully can give rough and ready answers. The remainder of this section describes several conditional projections to 1985, based on simple extrapolations of the exogenous variables and certain policy assumptions.

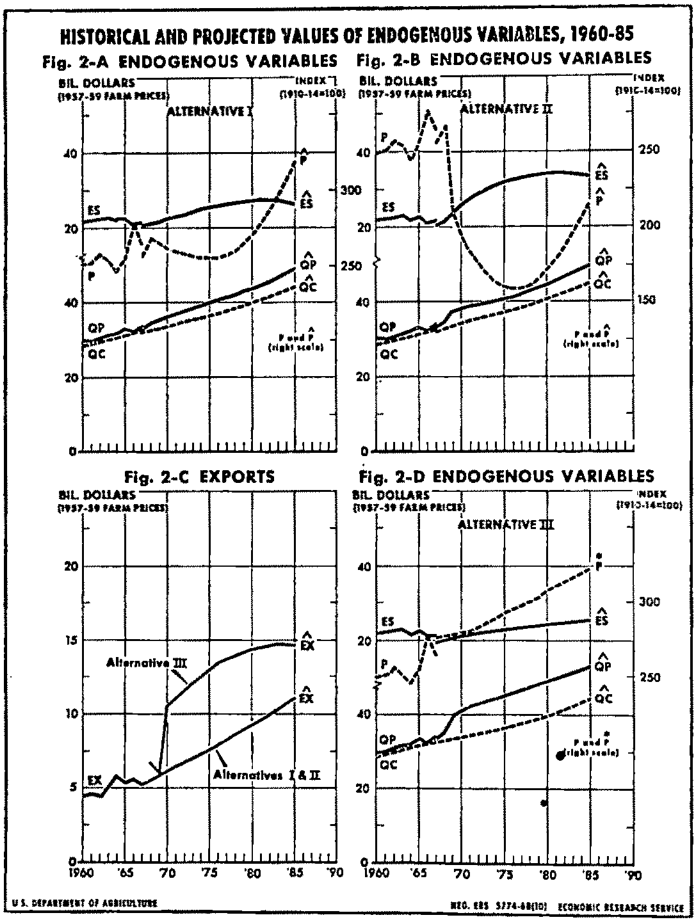
Alternative I assumes (1) that acreage diversions and price supports remain at the 1968 levels and (2) that other exogenous variables increase at their long-term trend rates over time, as follows:

	Percent per year
Prices paid for items used in production	0.9
Nonfood prices	2.4
Income per capita (current dollars)	4.6
Population	1.3
Imports	2.0
Exports	4.0

The conditional projections of the endogenous variables follow a somewhat unexpected pattern (Figure 2-A).[3] Even though output expansion is bridled by holding available cropland out of production, average prices are

---

[3] Data for all charts in this set and the supporting exogenous variables are available from the author on request.



HISTORICAL AND PROJECTED VALUES OF ENDOGENOUS VARIABLES, 1960-85

Fig. 2-D ENDOGENOUS VARIABLES

projected to decline moderately through 1974. After that year, demand expansion—domestic and foreign—catches up with output growth. Consequently, prices increase rather sharply up through the final year, 1985. But the estimated average price for 1985 represents only a rate of inflation equal to that assumed for prices paid by farmers. However, the validity of using a model which assumes a linear growth in output and a non-linear growth in domestic and foreign demand is subject to question. Specifically, output due to technology increases linearly over time, but the primary demand shifters—income and population—increase logarithmically.

The implication of the conditional projection is: Even if current programs are continued, additional land will need to be withdrawn from production in order to keep prices of farm commodities advancing at the same pace as other commodities, at least through the mid-seventies. Looking at it another way, this result indicates that surplus productive capacity in agriculture will continue to grow over the next several years.

Even though Alternative I indicates that surplus productive capacity may be increasing for some time, it should be instructive to look at the price consequences in agriculture of eliminating production controls or acreage diversions. This assumption provides Alternative II with the results shown by Figure 2-B. The acreage used in this analysis, 380 million, is an estimate of land that would be used for crops if all diverted cropland were returned to production, with some adjustment for double counting. This acreage, of course, does not represent the maximum amount of cropland that could be used for crops, but only the amount that likely would be brought into production in the absence of land diversion and control programs.

The index of prices received by farmers falls dramatically when diverted land is brought into production in 1969. It continues to fall through 1976, when, again, demand growth catches up with output increase. Despite the dramatic rise that is predicted to occur toward the end of the period, the average price is still below the current index. The wide swing in price that occurs under this alternative is due to the low price elasticities of demand for consumption and for stocks implied by the model. Small imbalances in supply and demand result in large changes in prices—an expected result, to say the least.

A number of alternative policy decisions could be investigated under our conditional projection procedure; alternative price supports or changing Food for Freedom exports, for example. More importantly, we might ask: Under what condition(s) could production restraints be taken off of farm production and reasonable prices be maintained?

Because it is quite obvious that domestic demand is unlikely to expand much further than projected in Alternatives I and II, the only conceivable outlet for "excess" production is exports. This proposition certainly is not new; it led to the development of P.L. 480 programs, although they were probably viewed as short-term measures rather than the continuing programs they have become.

Under Alternative III, exports are, in a sense, endogenous rather than exogenous. This variable is replaced in the exogenous set by the prices received index, which is assumed to increase at the same rate as the prices paid index. With this assumed steady increase in price, production, consumption, and stocks also increase at a steady pace over the projection period (Figure 2-D). Exports, on the other hand, would be required to follow a somewhat irregular pattern (Figure 2-C). But in the immediate years ahead, exports would need to increase dramatically—about 70 percent above the level now expected.

The likelihood of such an increase in commercial exports appears to be small. And unless support can be found for greatly expanded "food for peace" programs, which seems unlikely at the present time, the projected level of exports is unattainable.

Conclusions

The policy implication of the preceding analysis appears to be this: Some form of production controls will continue to be needed in agriculture to maintain farm prices and income, at least for the next decade. This situation will prevail unless technological advances and the amount of resources employed in agriculture can be brought into balance with output requirements. Market prices are not likely to bring about this balance. And, in consideration of the price gyrations that result from small imbalances in the agricultural sector, it is unlikely that public policy will be directed toward this end.

The simple model presented in this paper was designed to answer only gross questions about agriculture—its general structure, the nature and magnitude of the output imbalance. It appears to perform these functions quite well. But, as we move further and further into the future, its validity as a model of the gross structure of agriculture is expected to diminish. The level of aggregation also limits the usefulness of the model and probably reduces its precision. We are working on more elaborate models which include more detail (disaggregation) and a greater proportion of endogenous variables. The ultimate econometric model consists, obviously, of only endogenous, lagged endogenous, and policy variables. Econometric models, even the very sophisticated ones such as those developed by the Wharton school, the Office of Business Economics of the Department of Commerce, and the Social Science Research Council and Brookings Institution joint project are far from the millenium. However, in spite of their present limitations, they do permit a better understanding of the complex economic relationships involved, and even of the forecasting process.

APPENDIX

The Basic Data[4]

In general, all production, consumption, imports, exports and stocks are valued at average 1957–59 prices received by farmers [8].

Net agricultural production (*QP*) is the value weighted total agricultural production minus feed and seed used in the production process.

Net agricultural consumption (*QC*) is the value weighted total consumption of agricultural commodities less the same feed and seed subtracted from total production.

Total year-end stocks (*ES*) is the total value weighted stocks held by farmers, inventories held by marketing agencies and processors, and stocks owned by the Federal Government. Thus, it includes more than stocks on farms.

Exports (*EX*) is the value weighted total exports of agricultural commodities. Processed commodities are converted to farm equivalent before weighting.

Imports (*IM*) is the value weighted total of all competitive (e.g., beef)

---

[8] Bureau of Labor Statistics.

[9] Support prices of major price supported commodities weight by production.

ical viewpoint, an index that included wage would have been desirable. The index that includes taxes, interest and wage rates was not significant when used in the supply equation.

The weather index (*WI*) is the ratio of the index of crop production per acre to the estimated "normal" production per acre estimated by the equation $0=94.889\ 1.722\,t+.024\,t^2$, where t is the deviation from the mid-year 1953. This equation was fit for the years 1940 through 1966. The quadratic function gave a better fit than the semi-log or compound growth function.

Per capita income (*PI*) is per capita income in current dollars published by the Department of Commerce. The current dollar series was used because nonfood prices function as a deflator in the demand function.

Population (*POP*) is the total U. S. population, 50 States, including armed forces overseas, Bureau of the Census series.

Nonfood prices (*NF*) is the index of retail prices paid for all commodities less food, published by the Bureau of Labor Statistics.

Price supports (*PS*) is an index compiled by weighting the support prices for all supported commodities by their relative annual farm value.

A Policy for Public Investments in Natural Resources*

Melvin L. Cotner

Both pessimistic and optimistic views exist concerning the effects of resource scarcity on social welfare. Early classical doctrines that assume a fixed state of technology are the theoretical underpinning for the pessimistic view. But a new concept of resources has evolved in recent years that suggests the optimistic view. Resources can be created through science and technology. Existing resources can be made more productive and new resources can be created. Economic growth is a function of adequate resources to absorb investments. Resource creation and the improved use of existing resources, then, are key elements of a policy for public investments in natural resources. From a policy standpoint, public resource improvement investments must be compared with the social benefit streams created. Furthermore, these investments must be compared with alternative investment opportunities, such as extension-education programs, which would improve the use of existing resources.

IN this paper, an attempt is made to recapitulate the classical theory on resource scarcity and broaden it to represent new concepts about resource availabilities. Public policy implications of the broader theory are developed. Finally, principles for public investment strategies for resource development and general technology development are discussed.

Resource Scarcity Doctrines

Both pessimistic and optimistic views can be found among laymen and scientists that natural resources are scarce and are becoming more so. The pessimistic view obviously leads to questions about natural resource limitations on economic growth and the wise use of these resources over time. The optimistic view suggests that resource limitations can be circumvented.

Malthusian scarcity doctrine

During the early part of the 19th Century, Malthus postulated that population increases in geometric progression while means of subsistence increase arithmetically. Thus, in a matter of time, population eventually would begin to press on the means of subsistence. Modern theorists have classified this as the scarcity doctrine. According to this pessimistic view, natural resources, being nonreproducible, have a finite supply; and, as all of the available natural resources are brought into use, the law of variable

---

Melvin L. Cotner *is director of the Natural Resource Economics Division, Economic Research Service, U.S. Department of Agriculture.*

proportions comes into effect. The economy runs into diminishing marginal productivity of labor and capital as these factors expand against the fixed amount of natural resources.

As output per capita declines, the economic welfare of individuals is impaired. Likewise, if economic growth is measured by increase in output, diminishing returns slow the growth rate and ultimately, as output reaches a maximum, economic growth will cease.[1]

Ricardian scarcity doctrine

In its rigorous presentation, the Malthusian scarcity view assumes homogeneous resources and absolute limits on their availability. The scarcity model attributed to David Ricardo relaxes these assumptions by postulating that resources are available, but they have varying economic quality. As demand increases occur, resources of declining economic quality are employed. If, in fact, a society does call in the more productive resources first, then the diminishing productivity associated with increased resource employment would have a dampening effect on economic welfare and economic growth, just as in the Malthusian scarcity model.

Depletion scarcity doctrines

Nonreproducible resources can be depleted or destroyed over time. Stock resources and, to a certain extent, flow resources diminish with use. Soil nutrients, tree growth, minerals, ores, etc., are depletable. Associated with maintaining the renewable or flow resources is the problem of ecological balance. Damage to a single resource or element may deplete the aggregate of the resources available for man's use. The depletion and impairment of the natural balance of the earth's resources allow the Malthusian and Ricardian scarcity doctrines to be more severe. Diminishing returns become more acute and economic welfare and growth more limited.

Faith in Science Doctrine

While at any *given time* the supply of a particular material or group of resources may be limited, there is an optimistic view that over the *long run* the total supply of resources can be expanded. The technology and knowledge springing from science in effect can expand the supply of the resources, either in developing more resources in the same form as the original or by developing substitutes.

The new concept of resources is a dynamic view. As science improves and man's knowledge grows, increasing proportions of our total environment can be used to provide food, shelter, clothing, tools, energy, etc. At the present time, only a small proportion of our total environment is used for these purposes. Likewise, if we accept the view that there is an infinite amount of matter in total space, the horizons are unlimited. Furthermore, if matter is never destroyed by virtue of its being used, and only its current arrangement into useful resources is destroyed, then man needs only to resort to the process of science to develop some new (and perhaps improved) replacement or substitute resources.[2]

---

[1] For a discussion of these points, see [6, p. 23].

The implications of this view for economic growth and welfare are profound. There would be no resource limitation on growth. As pressures on resources mount and labor and capital experience diminishing marginal productivity, forces would be set off in the economy to develop substitutes for the resource. Economic welfare need not diminish because of resource scarcity as long as the forces of science and technology can be controlled and directed to this end.

This "confidence in science and technology" could lead resource users to proceed with reckless abandon. However, most individuals who hold the optimistic view also see the necessity of the wise use of existing resources over time. Moreover, technology development and resource improvement requires public and private investments that should be balanced against anticipated benefits. The wasteful use of resources would not be socially desirable. Rather than drift with population trends and technology, this group holds the view that society should strive for increasing control over the key factors in the population-resource problem. This process involves a systematic appraisal of trends in population, resources, and economic activities so that emerging problems may be foreseen and plans made for meeting them.[3]

The Theoretical Dependence of Economic Growth on Natural Resources

The scarcity doctrines can be summarized in geometric form so that the dependent relationships can be seen more clearly. The graphics herein are for explication only and are not meant to imply that broad resource problems have been refined for mathematical analyses. The primary purpose is to develop more explicitly the nexus between the "Malthusian–Ricardian scarcity doctrine" and "faith in science doctrine" and economic growth.

For purposes of clarification of the theoretical exposition, the concepts of economic growth and natural resources are defined.

Economic growth—Economic growth is the added economic activity generated through the utilization of resources to provide goods and services to include not only products and related services but environmental uses as well. For economic growth to occur, capital must be invested to provide new income earnings and, consequently, consumer demand activity. Not only must there be additional resources available for capital and labor investment, but there must be a demand for the goods and services from the resources—making investments attractive. Gross National Product, measured in constant dollars, is the direct measure of economic activity; consequently, the rate of change in real GNP is a measure of economic growth. Economic growth, just as economic efficiency, does not necessarily imply improvements in individual economic welfare and income distribution. Moreover, economic growth may not result in uniform growth among regions and localities. While these are worthy problems, the distributive aspects of growth are not studied in the subsequent analysis.

---

[2] For an excellent discussion of the technological advances on the horizon see [3, pp. 127–137].

[3] For a discussion of these views of "cautious optimism," see [4].

Natural resources—Resources are instruments of production that have economic usefulness. Natural resources are such nonreproducible and naturally replenished items as agricultural land, water, minerals, and ores that can be depleted but cannot be reproduced in their exact form, at least with current technology. Natural resources can be manipulated in several ways, anyone of which may be conscious policy objective. Resource use can be regulated so as to conserve, extend, or sustain its use over time. Resources may be depleted and used at exhaustive rates. Resources may be developed to improve their quality and availability over time. Parts of the environment may be combined into entirely new resources for which there is new demand. Accordingly, natural resource use and development is a dynamic process.

The static theory of resource scarcity

Classical theory, as discussed in the previous section, holds that limited resources will have the ultimate effect of restricting output in the economy. The presentation in this section has its roots in the writings of Adam Smith, Thomas Malthus, David Ricardo, John Stuart Mill, and Alfred Marshall.[4]

An aggregate production surface can be conceived where natural resources and nonnatural resources can be combined in varying proportions (Figure 1, chart 1). To be less abstract, one could conceive of an aggregate agricultural production process where units of land would be the resource inputs and the nonresource inputs would be labor and capital combined as a joint input. In a similar manner, the production surface is a composite of agricultural products, say food and fiber production, in this example. Each iso product curve from C_1 to C_6 represents larger amounts or levels of food and fiber production. An expanding population

(with resource productivity and technology levels constant)

(with increased technology attainment in nonresource inputs)

(with resource improvement)

Figure 1. Theoretical production relationships from various combinations of resource and nonresource inputs, assuming various levels of technology and resource improvement

in a growing economy presumably would employ resources and nonresource inputs in some combination in some expansion path from C_1 towards C_6. The output in this illustration is measured in monetary terms while the inputs are measured in physical terms. To maintain rigor in the presentation of the concept, the inputs must be of homogeneous quality throughout the range of use and the *ceteris paribus* conditions pertaining to all other variables must hold. A fixed state of the technical arts is an important assumption.

As an expanding society demands more food and fiber, consumers and resource owners should be interested in production patterns that are efficient. Given the production possibilities illustrated in Figure 1, the least costly production pattern and expansion path, *om*, can be derived if prices of inputs are known. A given sum of production capital can be invested to buy all resources, or, alternatively, all nonresource inputs *ol* could be purchased (see chart 1). An iso outlay curve, *rl*, can be derived representing varying proportions of the inputs that can be employed with the given sum or production capital. The C_2 iso product curve is tangent to the *rl* iso outlay curve at point *j* representing the highest product possible for the production capital considered. Alternatively, the production input mix at point *j* is the least costly way of producing the C_2 amount of food and fiber. The expansion path can be traced as increasing amounts of production capital are considered.

With unlimited quantities of resource and nonresource inputs, the expansion path in obtaining increased product is *om*. Resources would not restrict agricultural output. Output, of course, is limited, as the technology attainment assumed has a definite effect in shaping the production functions and their ultimate declining slopes. Output could exceed C_4 (Figure 1, chart 1).

The imposition of a limit on available resources such as *ae* has a distinct limiting effect on output as more nonresource inputs are applied. The expansion path is *od*. Output rises to a point below C_4, then would decline if producers tried to combine more nonresource inputs with the resources. Clearly, the nonresource inputs would be faced with declining productivity. Output in the producer's sector would be limited as a result of resource availability. A case does exist where technology implied in the production functions could become limiting before absolute resource availability would. In this instance, maximum physical product would be reached on the *od* expansion path and would experience a decline before reaching the physical limit of resources.

With resources employed at their limit, two potential economic effects become prominent. As the effective demand for output increases and as attempts to combine more nonresource inputs with limited resources are made, scarcity rents accrue to resource owners. A reciprocal of this effect is reduced payments per unit of nonresource inputs. Resource rents per *unit of output* would increase and nonresource costs per *unit of output* also could increase as larger amounts of nonresource inputs are applied. As a result, the price per unit of output would increase, making the total bill for goods and services from the producers sector higher.

One should note that there would be no economic incentive to push along the path *de*. In this example, some increase in productivity is possible through extended use of nonresource inputs, but declines in total physical productivity soon occur. Atomistic producers face perfectly elastic demand functions, thereby receiving erroneous economic signals to apply more nonresource inputs. If production was kept at *d*, the marginal productivity for nonresource inputs would not experience a decline.

The increase in rent to owners of limited resources implies an increase in asset values. Resource owners have control over a larger share of the wealth in the economy. Nonresource owners' earning capacity remains the same or is lower so they are not as well off relatively nor perhaps on an absolute basis.

In summary, the static theory of production, with all of the attendant assumptions of *ceteris paribus* conditions, does support the view that limited resources would have a negative or dampening effect on economic expansion and growth. Resource owners would gain asset values, while the earning power of other factor inputs would decline relative to that of resources.

Resource scarcity as related to propensities to consume and product demand elasticity

The ultimate effect of resource limitations on economic growth cannot be traced until the income recipients have utilized their income. Since nonresource owners have less disposable income and resource owners have more, there is potential for different propensities to consume that would have an effect on the economic activity generated through the income multipliers. One cannot say categorically that there would be less economic activity with shifts of purchasing power from non-resource owners to resource owners.

If resource limitation involves a product for which there is an elastic demand, the decrease in economic growth may be short-lived. An elastic demand suggests that alternate products could be used readily, thereby relieving the pressure on the product with limited resources. The effect on economic growth may be negligible also if the resource that is limited is small relative to the total of all resources used.

If the resource that is limited produces a product for which there are inelastic demand requirements and the product is a major one in the economy, then the effect on economic activity can be significant. In fact, an unstable situation would exist for major products having an inelastic demand and scarce resource inputs. Increased scarcity rents would provide income that, when spent, would create jobs, which in turn would create added demand for the product of the limited resources. If allowed to persist, the end effect would result in a concentration of wealth in the hands of resource owners. Accordingly, returns to non-resource inputs would be driven to the minimum level sufficient only to bring them into use.

The view that returns to nonresource inputs would reach minimum levels allowed the early classicists to label economics as the "dismal science," to identify "subsistence theories," develop the "iron law of wages" and predict wide scale famines. These are logical conclusions, given the static, changeless conditions believed to exist by these theorists.

Relaxation of the technology assumption

If the state of technical arts is allowed to change, resources may be less limiting in the production process (Figure 1, chart 2). Under conditions of an increase in general technology attainment, the expansion path, *of,* calls for different combinations of resource and nonresource inputs than under the initial technology assumption (compare charts 1 and 2). The physical quantity of the resource remains the same in chart 2. Even so, higher levels of product requirements can be produced before the physical limit is reached. Technology has the effect of increasing the amount of product attainable with a given level of resources. In chart 2, the C_3 level of production is obtainable from the *rl* outlay function. In chart 1, the same outlay produces the C_2 level only. Economic growth is fostered as inputs are released to be employed in other productive measures.

Well known examples of technology advances in agricultural production in recent decades are hybrid corn and other improvements in seed varieties. Widespread availability and use of inorganic fertilizer is another. These measures in conjunction with mass mechanization have had a significant influence on the culture of crop and livestock production. General technology, as conceived in chart 2 comes about through education and other so-called expenditures in human capital. Productive capacity is influenced indirectly through the improved know-how of the human inputs in the production process. Contrary to the views of the early theorists, the state of the arts does change. General technology has substituted for natural resources or, alternatively, has made resources more productive. In fact, technology has increased sufficiently so that abnormally high natural resource rent and product price rises have not come about.

Introduction of resource improvement

Improvements in the natural resources can have an effect similar to that of a general technology increase (Figure 1, chart 3). Any measure that has the effect of improving the productivity of the natural resource also has the capacity of reducing the resource scarcity effect. The expansion path is *ob* with resource improvements. Again, higher levels of product are attained before the absolute limit on resources is reached. In the illustration, resource improvement allows output to be produced with considerably less inputs.

Resource improvement or development is another form of technology. The distinguishing feature of resource development is its physical link with the resource. Public expenditures can be applied directly to influence productive capacities of the resources. Agricultural land drainage is an example. Tile drainage, in a strict sense, may be a technological improvement, but it is considered resource development because of its unique spatial relation to the resource. The agricultural land resource has been improved. Large sums in both the private and public sectors have been spent to clear, drain, and irrigate land. These improvements, when coupled with general technological improvements, have lessened the negative effect of resource scarcity on economic growth.

Dynamics of resource use

Schultz states that economic growth results from a dynamic disequilibrium [7, p. 27]. As demands shift, opportunities to utilize existing resources or develop substitute resources with a high payoff come into existence. As the resources are developed and the particular demand satisfied, rates of return on investment decline, thereby slowing the productive investments and deterring economic growth. To make economic growth a continuous positive function, new or expanding demands and new sets of resources or improved existing resources must be available for productive use. The maintenance of an ample and relevant set of resources in which investments can be made are of primary concern to a society interested in economic growth.

A product requirement of C_4 under the assumptions in Figure 1, chart 1, is unattainable. As attempts are made to achieve this product, economic growth would tend to be dampened as labor and capital productivities decline. The degree that economic growth is sloped depends upon the elasticity of demand for the product from the limiting resource and the size of the product market relative to the whole economy. But this is a disequilibrium that will call for corrective measures, provided, of course, that an adequate institutional framework exists in the public and private sectors of the economy. The higher profits (rents) to the resource provide the incentive for technological inputs to capture some of the abnormal rents. With an increment of general technology as assumed in chart 2, resource earnings would be diverted to nonresource inputs. The new inputs, which really are manifestations of new resources, are applied until the new demand requirement is satisfied. The new inputs also could become scarce, command abnormal rents and entice substitute inputs. Resource managers must be ingenious and be innovators if measures to correct the dynamic disequilibrium forces are to be most effective. In fact, one could generalize the healthy economy as one in which there could be many resource barriers, but knowledgeable entrepreneurs are adopting technology to circumvent the resource problems. Shifts in the productive capacity of resources such as shown in charts 2 and 3 must come about if economic growth and a full employment economy are to be sustained. Presumably, some mix of public expenditures for research, extension education, and resource improvement will facilitate the dynamic adjustment process.

One can conceive of a grand strategy to minimize the effects of resource limitations on economic growth. The theory summarized in this section suggests that as the original supply function of a resource becomes more inelastic, the scarcity returns potential becomes great. Further, the theory indicates that as the demand for the product of a limiting resource becomes more inelastic, the potential effect in limiting growth is greater. The strategy through time, perhaps, would be to concentrate public investments in the area of those conventional resources most likely to inflict diminishing marginal returns on other inputs, thus expanding productive capacity as conceptualized in charts 2 and 3 of Figure 1.

In the public sector, decisions about investments of public funds in general technology development and specific resource development can be subjected to the marginal calculus of economics. In general, the stream of social benefits from public investments in increasing the nation's productive capacity should be equal to or greater than the stream of social benefits in the private purchasing power foregone in the investment.[5] If the marginal increase in productive capacity and resulting stream of social benefits is smaller than the increment of public investment and its opportunity costs if left in the private sector, the expenditure would have a negative impact on economic growth. The above criteria relate only to the magnitude of economic activity and not to the effect on the distribution of personal utility streams. As indicated, wealth distribution is an extremely important problem, but is not analyzed here.

Presumably, there is a functional relationship between investments in research, education, and extension activities and shifts in the productivity capacity of the nation's resources. Likewise, public expenditures in making resources more productive are functionally related. A basic question arises: Can a society expect increasing, constant, or diminishing returns to resource improvement and general technology development expenditures?[6] Within a given state of the art, diminishing returns do occur. But in a dynamic sense, can the state of the art be expanded indefinitely without incurring increasing costs? As a society advances in a more complex and rapidly changing environment, conceivably the limiting resource will be the capacity of the human factor to keep pace by providing new technology. Public decisions can be improved if these functional relationships are known, and meaningful information on public and private costs and benefits are developed.

---

[5] The productivity criterion for public expenditures is advanced by James Buchanan [2].

Policy Implications

The principal policy implication to be drawn from the discussion in this paper is that positive actions should be undertaken to insure that resource barriers do not become critical and that losses in economic activity are minimized. To achieve sustained economic growth, adequate institutional arrangements must be provided. Presumably, public investments to assist in the development and adoption of technology in relevant areas are justifiable uses of public funds, given favorable benefit and cost relationships.

But there are questions about the role that public agencies should play in directing the flow of resource creation. Some fiscal theorists argue that government should play a passive role in resource allocation and development schemes. In other words, the public programs should not alter the workings of the market in the private sector in calling forth resources and employment. In this view, the government would undertake only those measures necessary to soften temporary cyclical adjustments in the economy. Other fiscal theorists argue that there is a persistent and chronic gap between full employment and existing employment levels. With the Employment Act of 1946, this group feels that policy and responsibility of the Federal Government becomes one of coordinating and utilizing its functions and resources to achieve maximum employment, production, and purchasing power.[7]

Those who argue for a passive role of government must concede that all public actions, including decisions not to act, have a definite influence on resource allocations. Therefore, the acceptance of either political philosophy should not preclude research and analyses of the potential gains and losses of alternative public actions in the resource area and an analysis of constructive means and priorities for alleviating resource problems.

---

[6] Schultz raises this question and suggests that research "may well be in its increasing returns phase." He makes no prognostication on this point except that "returns to these inputs to society are large (and will be) substantially larger than returns from most alternative uses" [8].

[7] For a presentation of the Heller-Burns arguments on these points, see [5].

Policy for research and extension education investments

The public policy for research and extension education should be one whereby resource creation from such expenditures is adequate to achieve the desired growth and employment goals of society. The criterion involves comparisons of the value of the public investment with the value of the employment or economic activity created. As indicated previously, if the research and education investment is not productive of new streams of economic activity, the measure does not contribute to economic growth. Research and education investments should be compared with alternative investments that increase productive capacity, such as direct public expenditures in resource improvements.

The ability to predict the increase in productive capacity associated with public research and extension educational expenditures is difficult. But if knowledgeable policy decisions are to be made about the use of public funds for research and extension education expenditures to develop and encourage the adoption of technology, estimates of these functional relationships are necessary. Research and extension education expenditures in many cases may well be a better use of available public funds in attempts to minimize the negative effects of limited resources on economic growth. Such hypotheses are in need of empirical verification.

Policy for public investments in natural resource improvements

Public policy for resource improvement also should be one whereby the productivity of our stock of resources is adequate to achieve the growth and employment rates desired by society. In a manner similar to that suggested for research and extension education investments, public resource improvement investments must be compared with the social benefit streams created. For instance, certain social benefits are associated with public cost-sharing arrangements with private resource owners to encourage agricultural land drainage. Similar relationships exist for public investments for irrigation, water quality improvement, recreation development, provision of open space, and so forth.

The theory presented in this paper indicates that public resource improvement or development is clearly an alternative and complement to public research expenditures to promote general technology adoption in preventing negative impacts of scarce natural resources. In the final analysis, some combination of expenditure on research and extension education to indirectly influence productive capacity with direct investment on already-known techniques of resource improvements would be ideal. To properly apply these criteria, considerable information is needed on the functional relationships of the alternative uses of the public monies.

Analytical schemes are needed to inventory current and potential resource problems. An analytical procedure is needed whereby resource problems can be placed in perspective and the effects of alternative public resource development and assistance measures can be identified.

An Analysis of the 1964 Wheat Option

MAX MOSZER

Wheat farmers operate in a quasi free market in which guaranteed price minima are available upon satisfaction of governmental imposed preconditions. A method is developed with which farmers can evaluate the profitability of available alternatives. In general, there must be sufficient land so that the acreage of wheat relative to the allotment exceeds the ratio of the loan rate to the expected free market price. These break even criteria can be used by policy planners to evaluate proposed programs and to determine their efficacy before their implementation. Ideally, programs should be structured so that the most profitable alternative for the farmer is also the one that will achieve the policy goal. An analysis of statewide aggregate data confirms the theoretical conclusion, based on this methodology, that full participation without additional voluntary diversion was the most profitable alternative open to the wheat farmer in 1964.

THE purpose of this paper is to suggest a method of analysis with which to estimate reaction patterns of large groups when inadequate data exist or when the available information is too cumbersome to be used purposefully. This technique will be demonstrated by an analysis of the 1964 Wheat Option. This is, however, a general method; it can be applied fruitfully by legislators and policymakers in any situation to gain perspective and a first, *quantitative* approximation of a proposal's efficacy. Such a tool is of special interest and importance for agriculture, since much of its output is subject to constantly changing legislation in the face of persisting maladjustment.

The scheme utilizes the conventional, static theory of the profit maximizing firm; it makes assumptions and abstractions as they become necessary. Experts in the area may question the particular assumptions and propose less heroic and less fruitful ones. One purpose of this paper, however, is merely to suggest a relevant technique.[1] It must be remembered that its methods are also subject to the basic criterion employed in the analysis: Marginal Revenue = Marginal Cost.

Provisions of the 1964 Wheat Option

The 1964 program was significantly new; it provided for a two price market, as well as mandatory and additional voluntary diversion, and it eliminated quotas and penalties for selling wheat in excess of the harvest of the acreage allotment. It was a voluntary program: there were no penalties—aside from the pecuniary ones of the market—on farmers who did not wish to comply with the program.[2]

---

[1] A paper in a similar vein, dealing with white collar crime, is in preparation by the author. It proposes alternate procedures by which the rate of collection of taxes due may be increased.

[2] The legislation that authorized this program resulted from the 1963 defeat of the 1964

MAX MOSZER *is associate professor of economics at Kent State University.*

The program enabled each farmer to choose from three options: (1) noncooperation, which permitted unlimited production but afforded no price support of any kind; (2) partial participation, which provided price support for farmers who complied with the acreage allotment; and (3) full participation, which required a minimum diversion of 11.11% of the allotment, permitted additional diversion of up to 20% of the allotment, and provided nonrecourse loans on the harvest, a direct diversion payment, and payments of marketing certificates[3] on the normal yield of the diverted and harvested acreage, respectively.

Achievement of the policy goals of this program depended upon the alternative chosen by the farmer, which in turn depended upon his evaluation of the course that would maximize his profit on wheat, consistent with the restraints of the market, technology and substitutability of his particular class of wheat, and his other crops. His options are summarized in Table 1.

Table 1. 1964 wheat program alternatives

	Non-cooperation	Cooperation	
		Partial participation	Full participation
Acreage limitation	none	allotment	allotment (1.0–.1111)
Loan rate	not available	\$1.30/bushel	\$1.30/bushel
Mandatory diversion	—	none	.1111 allotment
Voluntary diversion	—	—	up to .2 allotment (total allotment if it is no greater than 15 acres.)
Diversion payment	—	—	.2 of the county loan on normal yield of diversion
Marketing certificates	—	—	\$.25+(\$.45 on 45%) on normal production of the net acreage

Source: [10].

The Analytical Method

Noncooperation is the more profitable alternative only if

$$PCY^* - T_p > ALY^* - T_a \tag{1}$$

where

P = the planted acreage,
A = the acreage allotments,
C = the expected cash or free market price of wheat at harvest,

---

Marketing Quota Referendum. For a comprehensive, historical view of wheat programs, see [1] and [3]. The latter and [2] present analytical material as well.

[3] These were the mechanism by which the multiple price structure of wheat was implemented.

L = the nonrecourse loan rate,
Y = the normal yield,
Y^* = the expected yield, and
T = the total cost of production, sub a and sub p on the allotted and planted acreage, respectively.

Equation (1) can be restated as a decision making, break even criterion in the form of

$$\frac{P}{A} > \frac{L}{C} + \frac{T_p - T_a}{ACY^*}\,. \tag{2}$$

Noncooperation is more profitable only if the left-hand side is greater than the right-hand side of (2). This occurs when the ratio of planted to allotted acres exceeds the ratio of the loan to the expected cash price plus a term in costs. In terms of decision making, (2) indicates that noncooperation is the more profitable alternative only if the farmer has sufficient crop land available to make the overplanting ratio greater than the right-hand side. Since A, L, P, and the costs are known at the time the decision must be made, it is possible to combine this information with the farmer's estimate of the future market price to arrive at a rational estimate of the more profitable course.

The cost term in (2) can not be very large. It is the reduction in cost[4] resulting from producing on fewer acres divided by a large number. The divisor approximates total revenue—it is (C/L) as large as the revenue of the cooperator and (A/P) as large as the revenue of the noncooperator. It is not unrealistic to assume that the out of pocket costs of the smaller farmer are the same for both acreages. Then the change in costs is equal to zero and the second term in (2) disappears. If the assumption of constant unit cost is made for larger farms, the cost reduction term also disappears.[5] If the average cost of the smaller acreage is less than that of the larger acreage—$b<a$—there will be a negative bias to the criterion. However, its order of magnitude is small and known. Ideally, the analysis ought to find the most *profitable* alternative but, as has been shown, there is no great difference between revenue and profit maximizing criteria. Accordingly, because of the simplicity, the criteria will be expressed in terms of revenue alone.

---

[4] It is the marginal cost of $(P-A)$ acres.

[5] Substitute $T_p = a(PCY^*)$ and $T_a = b(ALY^*)$, where a and b represent the average cost respectively of the noncooperator and of the cooperator, in (2) to yield

$$\frac{P}{A} > \frac{L}{C} + \frac{a(PCY^*) - b(ALY^*)}{ACY^*}\,.$$

This reduces to

$$\frac{P}{A} > \frac{L(1-b)}{C(1-a)}$$

and when $a=b$, the criterion is in terms of the price ratio only.

Evaluation of the Alternatives: Revenue Maximization

Let R_n, R_p, and R_f represent the total revenue earned from noncooperation, partial participation, and full participation respectively. Then, from the provisions of the law, as outlined in Table 1, and substituting the 1964 numerical values when convenient,

$$R_n = P \cdot Y^* \cdot C \tag{3}$$

$$R_p = A \cdot Y^* \cdot L \tag{4}$$

$$R_f = .8889\ (A \cdot Y^* \cdot L) + \$.4275(A \cdot Y) + .02222(A \cdot Y \cdot L). \tag{5}$$

The revenue of the noncooperator is greater than that of the partial participator as long as (3) is greater than (4), or as long as $(R_n/R_p) > 1$,

$$\frac{P}{A} > \frac{L}{C}\,. \tag{6}$$

In other words, for noncooperation to be the more profitable action, the overplanting ratio must exceed the loan rate to the expected cash price ratio.[6] This is identical with the 1938 Act.[7] Of course, when the loan rate is less than the cash price, noncooperation is always more profitable. The incentive for staying within the allotment is the availability of the nonrecourse loan and this is meaningful only when it is greater than the free market price.

The comparison of the noncooperator and the full participator yields, as the ratio of their revenues,

$$\frac{R_n}{R_f} = \frac{P \cdot C}{A \cdot L\left(.8889 + \frac{Y}{Y^*}\left(.0222 + \frac{\$.4275}{L}\right)\right)} \tag{7a}$$

or

$$\frac{R_n}{R_f} = \frac{P \cdot C}{A \cdot L\left(.8889 + .351\,\frac{Y}{Y^*}\right)}\,. \tag{7b}$$

For overplanting to yield a greater revenue than full participation, it is necessary that

$$\frac{P}{A} > \frac{L}{C}\,k. \tag{8}$$

This is identical with equation (6) except for the factor k, which stands for the bracketed terms in the denominator of (7b). The previous analysis therefore stands, and when $k>1$, cooperation is more profitable, all other things being equal.

---

[6] This abstracts from the consideration of alternative crops. The problems encountered and the break even ratio associated with the lifting of this assumption are discussed in [3, p. 77].

[7] See [3] for the criterion applicable to this law.

The value of k depends on: (1) the legislated loan rate, (2) the legislated diversion payment, (3) the ratio of normal to expected yield, (4) the legislated minimum diversion to qualify for marketing certificates, and (5) the legislated value of the marketing certificates. Increasing the loan rate decreases the value of k,[8] while increasing the diversion payment and the certificate value increases k. Increasing the qualifying diversion percentage changes the value of k by

$$-1+\frac{Y}{Y^*}V_3, \quad \text{where} \quad V_3=\frac{\text{Diversion payment per acre}}{\text{Loan rate}}.$$

Since the yield ratio is usually less than one (see below), increasing the threshhold diversion, *cet. par.*, reduces k and the effectiveness of the program.

The yield ratio is nominally beyond the farmer's control; a decrease in the expected yield will increase the value of k. The 1964 data, $k=.8889+.351(Y/Y^*)$, require the yield ratio to $\geq .3174$ for $k\geq 1$. This occurs as long as $3.15Y\geq Y^*$, i.e., when the expected yield is less than 3.15 times as great as the normal yield. Since normal yield is defined as the average yield of the past ten years, one would expect this ratio to approximate unity; with a positive time trend of yield, the ratio would be somewhat less than one.[9]

Ordinarily, then, $k\geq 1$; this makes the option of full participation more attractive than the conventional allotment scheme without quotas. It is interesting to comment on the implication of the values of k. When a bumper yield is anticipated, the ratio of normal to expected yield becomes very small. For example, if the yield is expected to be five times as great as ordinarily, k will become much less than unity, but it must be >1 to increase the profitability of full participation. Thus, this program is perverse. In bumper crop years, farmers will be encouraged to plant more, while in lean years, co-

---

[8] The whole right-hand side of the criterion increases, however, since L enters k with a factor equal to the value of the marketing certificate.

[9] Assuming that the yield increases at compound interest at the rate a, then the average yield over a ten year period will be $(1/10a)Y_0((1+a)^{10}-1)$, where Y_0= the yield of the first year. This is the numerator of the yield ratio. The denominator, the expected yield of the 11th year, is simply $Y_0(1+a)^{10}$ so that the yield ratio is

$$\left[\frac{(1+a)^{10}-1}{10a(1+a)^{10}}\right].$$

As long as the rate of increase is less than 28% per year, the yield ratio will be $>.3174$. For the values of 1964 it is almost impossible for k to be less than 1.

In 1954, the average yield of all wheat classes was 18.1 bushels per harvested acre and for 1963 it was 25.3 bushels. This increase of 7.2 bushels over 10 years is at a compound rate of interest of about $3\frac{1}{2}\%$. Substituting $a=.035$ in the above equation results in a yield ratio of .836 and $k=1.18$ for 1964. Interestingly enough, 103.5% of 25.3, the 1963 yield, is 26.17. This is almost identical to the reported yield of 26.2 bushels per harvested acre in 1964.

certificates were not withdrawn, the yield ratio would have to be as great as five to make the tradeoff profitable.

It is interesting to see whether inclusion of costs in this calculation would alter this conclusion. Add the change in total cost, ΔT, to the total-change-in-revenue equation. The change in profits, then, equals

$$L(.008Y - Y^*) - \Delta T. \tag{9}$$

Additional diversion is profitable if this expression is ≥ 0, where the change in T is negative. This occurs only when

$$\frac{Y}{Y^*} \geq 125\left(1 + \frac{\Delta T}{Y^*L}\right). \tag{10}$$

To avoid the problem of estimating costs[12] for all states, first state costs as some proportion of revenue, Y^*L, and then assume that the marginal cost of the last acre is equal to $c \cdot (Y^*L)$; the revenues cancel out and, since we are dealing with decreasing output, $c \leq 0$.[13] Clearly, when $c = 0$, i.e., when cost savings are zero, this gives the same results as before: the yield ratio must exceed 125 to make additional diversion profitable.

When costs incurred in the production of the last acre are equal to the revenue received, $c = -1$. It will always be profitable to divert this acre. Substituting $-Y^*L$ for ΔT in the original profit definition, it is seen that the increment to profit is $.008Y \cdot L$. Thus, for 1964, when the loan rate was \$1.30, each additional acre diverted would have increased profits by \$.0104 times the normal yield per acre. Assuming a normal yield of 30 bushels per acre, the reward would be on the order of 32 cents per acre of additional diversion.[14]

The addition of costs do not change the previous analysis; it can be concluded, then, that abstracting from cost considerations does no violence to the results. This conclusion, however, may not hold for those farmers who are allowed to divert their total allotment (if it is no more than 15 acres). On these small farms, significant cost reductions might occur when the wheat operation is shut down. It might be implausible to operate two or three acres; the costs of production and/or sales or marketing might be excessive. Furthermore, the opportunity cost of other occupations or endeavors might be greater than the profit from such small acreage.[15]

---

[12] See footnote 5 above.

[13] The argument might be made that the normal yield rather than the expected yield should be used for the cost function. Obviously, this complicates the expression. Costs do depend on the amount of wheat harvested which, of course, is a function of future yield. Moreover, Y can be expressed in terms of Y^* and the last term cancels out again.

[14] It will be recalled that if the export certificates were not lost when additional diversion occurred, the factor on the right-hand side would be reduced to 5. The increment to profit, when cost equals revenue, then would be $.2Y \cdot L$ or \$7.80 per acre.

[15] The additional diversion calculation was basically the same for the 1965 program even though the numerical provisions had been changed significantly. Diversion of the first 11.11%

To sum up, since k ordinarily is greater than 1.0, full participation is (1) more attractive than partial participation and (2) will be limited to the mandatory 11.11%—i.e., voluntary diversion will not occur. For 1964, k equalled 1.18 (see footnote 9); substituting this value in equation (8), the required overplanting ratio = 1.54. It can be concluded, then, that unless the farmer had this amount of land available,[16] he would have found full participation without additional voluntary diversion the most lucrative alternative.

Policy Evaluation of the Program

The obvious goal of the 1964 wheat program was to reduce production by means of free choice by all wheat farmers. This production goal was formulated in acres rather than bushels and in terms of the U.S. total rather than individual farms. It is possible to predict, *ex ante*, the efficacy of a given program to achieve the goal by applying the individual farmer's evaluation on a global basis.

Comparing the alternatives of noncooperation and partial participation and assuming that the loan were greater than the cash price, the possibility of the farmer receiving a greater revenue from noncooperation depends upon the availability of land. At the time the program and the $1.30 rate were announced, it was speculated that 1964 wheat might sell for as little as $1 a bushel. Since the allotment was at the statutory minimum of 55 million acres while planting had exceeded 70 million acres several times in the past, it may be concluded that it was possible to overplant by more than 130% of the allotment. Moreover, some farmers might well have discounted the dollar wheat forecast as propaganda to encourage enrollment in the program. Thus the necessary overplanting ratio would be smaller than 1.3; in other words, the amount of overplanting needed to gain the same revenue as

---

of the allotment was mandatory for participation, as in 1964. Diversion of the next 10% was not paid for, although the certificates were not reduced either. Further diversion of up to 10% more would be paid at 50% of the loan rate, without loss of certificates. The criterion for comparing total revenue now becomes $(Y/Y^*)>2(1+.1/t)$, where t is the paid diversion as a fraction of the acreage allotment. Thus $0\leq t\leq .1$. Clearly, the 1965 program is more conducive to additional diversion than the previous one. In 1964, additional diversion increased revenue only when the yield ratio exceeded 125. Presently, if the farmer electes to divert the maximum percentage for which he will receive payment, the yield ratio need only exceed 4. Moreover, the program now encourages lump diversion whereas the earlier one did not. The required yield ratio declines at an increasing rate as the diversion percentage of the allotment increases. In 1965, as before, including the cost saving in the calculation requires the yield ratio to exceed $2(1+.1/t)\ (1+\Delta TC/LY^*)$. Making the same assumption on the relationship between cost and revenue, it can be seen that the 1965 program does bring the yield ratio into plausible ranges. The payment for the maximum diversion of 20% at 30 bushels per acre normal yield would now be $18.75 per acre. Clearly the revision made this part of the program more effective.

[16] One must consider total, not just wheat, land. The provision of this program may make alternate crops more or less profitable. However, the Act did not become law until April 11, 1964—far too late to make necessary adjustments. In fact, diversion was defined by the Department of Agriculture as abandonment.

the partial participator would be reduced and the possibility of profitable overplanting enhanced. While the additional cost of planting in excess of the allotment might be greater than the increment to revenue, we cannot draw the conclusion from the provisions of this law that noncooperation is less profitable than partial participation. On the other hand, the possibility exists that overplanting is perhaps the more profitable alternative.

Equation (8) can be used similarly to evaluate the noncooperation-full participation alternative. Substituting the 1964 values, it is found that the acreage required to make noncooperation yield greater revenue is just beyond the border line of feasibility. With the yield ratio of .835 giving rise to a k of 1.18, the right-hand side of the revenue criterion is 1.54 (1.18 times the L/C ratio of 1.3). That is, the planting of the noncooperator had to exceed 154% of the allotment in order to earn the same revenue as the participator. On a national scale, this required a planting of 84.7 million acres instead of the 55 million allotted acres. The largest wheat planting of record occurred in 1949, when 83.9 million acres were seeded. Since that time, about 5 million acres had been placed in the long range Soil Bank and could be considered unavailable even in 1964 [6, pp. 30–61]. When these national totals are applied to the individual farm, it is then not too tenuous to conclude that there was not sufficient acreage available to earn total receipts equivalent to those available to the full participator.

By using the break even criteria developed in the previous section, the policymaker could have estimated the extent of farmer participation and the success of the program. Moreover, the policy purpose of legislation can be implemented by assigning values which would make profitable overplanting impossible. The profit maximizing farmer would find that, even though cooperation is odious to him, he does not have sufficient acreage available to earn as great a revenue as could be gained from participation.

These conclusions, even though based on aggregates, are valid. The policymaker need not know the reaction of each farmer, nor even that of the average farmer;[17] it is sufficient for him to have the total response of all farmers. Clearly, all farmers can not overplant enough to make the program a failure—85 million acres of wheat—even though some farmers might decide to do just that. The global acreage just is not available.

The Effect of Yield on Program Evaluation

Equations (7b) and (10) express the break even ratios in terms of the ratio of normal to expected yield. This section examines whether and how changing yield and yield expectations affect the conclusions derived so far. To do so, it is necessary to differentiate the right-hand side of the revenue criterion with respect to Y^*, the expected yield. It is advantageous to develop the general case in terms of the following symbols, rather than the values which prevailed in 1964:

---

[17] That is not to say that he would not *like* to know individual reactions—it is just that he can not get this information.

Let D = the proportion of acreage which must be diverted to qualify,
V_1 = the dollar value of the domestic marketing certificate,
V_2 = the dollar value of the foreign marketing certificate,
V_3 = the percentage that the diversion payment is of the loan rate,
E_1 = the proportion of the allotment eligible for domestic certificates, and
E_2 = the proportion of the allotment that is eligible to receive foreign marketing certificates.

Assume, for the sake of simplicity, $E_1+E_2=1-D$; i.e., that certificates will be issued on all the acreage which remains of the allotment after deducting the qualifying diversion.[18]

The total revenue of the full participator, then, is the sum of

$(1-D)\ AY^*L$—from the production on the net allotted acreage,
$V_3L\ DAY$—the diversion payment,
$V_1E_1\ AY$—domestic marketing certificates,
$V_2E_2\ AY$—foreign marketing certificates, and

$$R_f = AY^*L\left[(1-D)+\frac{Y}{Y^*}\left(E_1\frac{V_1}{L}+E_2\frac{V_2}{L}+DV_3\right)\right]. \tag{11}$$

The revenue comparison between the noncooperator and full participator is, as before,

$$\frac{P}{A} > \frac{L}{C}K' \tag{12}$$

except that K' replaces the k of (8) and now stands for the expression in the brackets of (11).

In order to evaluate the effect of a change in the expected yield, we differentiate—with respect to Y^*—the right-hand side of (12), the break-even criterion:

$$\frac{-\frac{C}{Y^*}\left[L\frac{Y}{Y^*}K\right]-\left[L\frac{Y}{Y^*}K+L(1-D)\right]\frac{dC}{dY^*}}{C^2}, \tag{13}$$

where

$$K = E_1\frac{V_1}{L}+E_2\frac{V_2}{L}+DV_3.$$

---

[18] This seems to be consistent with the intent of the legislation and its administration. While the diversion percentage was 11.11, the marketing certificates were to be issued on 90% of the allotment. The 1965 program increased the minimum diversion by 10% while the total issue of certificates was restricted to 80% of the allotment.

When (13) is positive, an increase in Y^*, the expected yield, increases the required overplanting ratio; when it is negative, rising yield expectations reduce the ratio. To evaluate the sign of (13), neglect the always positive denominator and split the numerator into two parts: the terms weighted by dC/dY^*, the indirect effect, and the first term, the direct effect of a change in the expected yield on the break even ratio. The sign of the direct effect is the opposite of dY^* and thus, as discussed above, it always has a perverse effect: overplanting is more profitable in bumper crop years and less profitable in bad years. In order for (13) to have the same sign as the change in expected yield, dC/dY^* must be negative and the indirect effect must be greater, in absolute terms, than the direct effect. For a given demand curve and acreage, i.e., *cer. par.*, prices and yields move in opposite directions. Therefore, it is possible for these two effects to offset each other. The program, then, is perverse, neutral, or salutary if the absolute value of the direct effect is greater than, equal to, or less than the absolute value of the indirect effect. After manipulating the numerator to

$$-\frac{YK}{Y^*}(1+e)-(1-D)e, \quad \text{where} \quad e=\frac{Y^*dC}{dY^*C}, \tag{14}$$

the test condition becomes

$$\frac{YK}{Y^*(1-D)}=-\frac{e}{1+e}\,. \tag{15}$$

The program is salutary, neutral, or perverse, as the right-hand side is greater, equal to, or less than the left-hand side. Clearly, when $dC/dY^* \geq 0$, the elasticity coefficient is positive, the right-hand side is less than or equal to zero, and is also less than the left-hand side of the test condition; the program is perverse. It is a necessary—but not sufficient—condition that $e<0$ for the program to be salutary. If e is greater than the absolute value of minus one, the right-hand side becomes negative, and the program is perverse in this range also. On the other hand, the elasticity must be large enough—in absolute terms—to exceed the value of the left-hand side. When the two sides are equal, on the borderline, the program is neutral.

What is the elasticity which equates these two terms? This depends on the values of Y/Y^*, K, and $(1-D)$. Substituting the 1964 rates for the latter two terms and assuming the yield ratio to be unity, the required elasticity is $-.28$. This means that if a 10% increase in the expected yield creates a 2.8% decrease in price expectations, the program is neutral. A more responsive elasticity, provided it is $<|-1|$, will cause the break-even criterion to assume values which will make overplanting less profitable. Lifting the assumption on the yield ratio, we see that the required elasticity falls as the expected yield increases (relative to the normal yield). This is shown in Figure 1. Values below and to the right of the curve indicate that the program is salutary; those to the left and above mean that it is perverse.

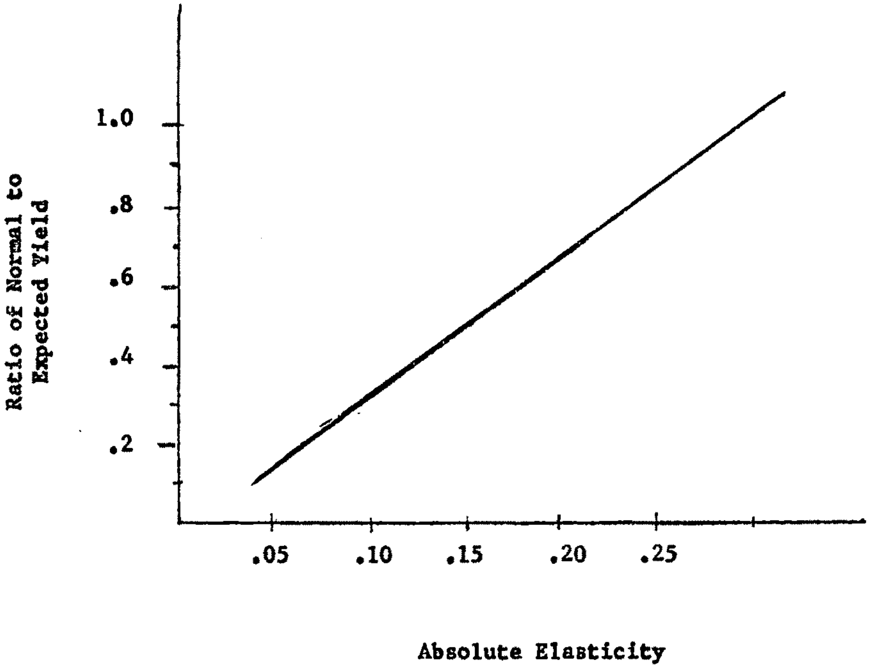

FIGURE 1. Minimum elasticity required for neutrality of 1964 program

While it is not possible to quantify or measure the elasticity of expected prices with respect to expected yields,[19] it seems that the requirement that it be $\leq |.28|$, when the yield ratio is unity, is not so great as to rule it out of the realm of possibility [5].

If it is assumed that a linear relationship exists between C and Y^*, then, as Y^* increases, the yield ratio falls and the required elasticity for neutrality falls, but the actual elasticity rises. This makes the outcome more favorable. The most advantageous assumption for a salutary program is that $d^2C/(dY^*)^2>0$. An increase in the expected yield then causes the elasticity to increase even more. Moreover, this seems to be the most logical assumption. The magnitude of the change in the expected cash price varies directly with the size of the expected yield change (as the yield ratio departs from unity). This relationship is shown in Figure 2.

There is yet another explanation which makes the assumption of the increasing (in absolute terms) slope of the $C-Y^*$ relationship more accept-

---

[19] But see Nerlove [4] on this for the necessary assumptions in order to use the technique developed by him to measure responses to expected values of variables.

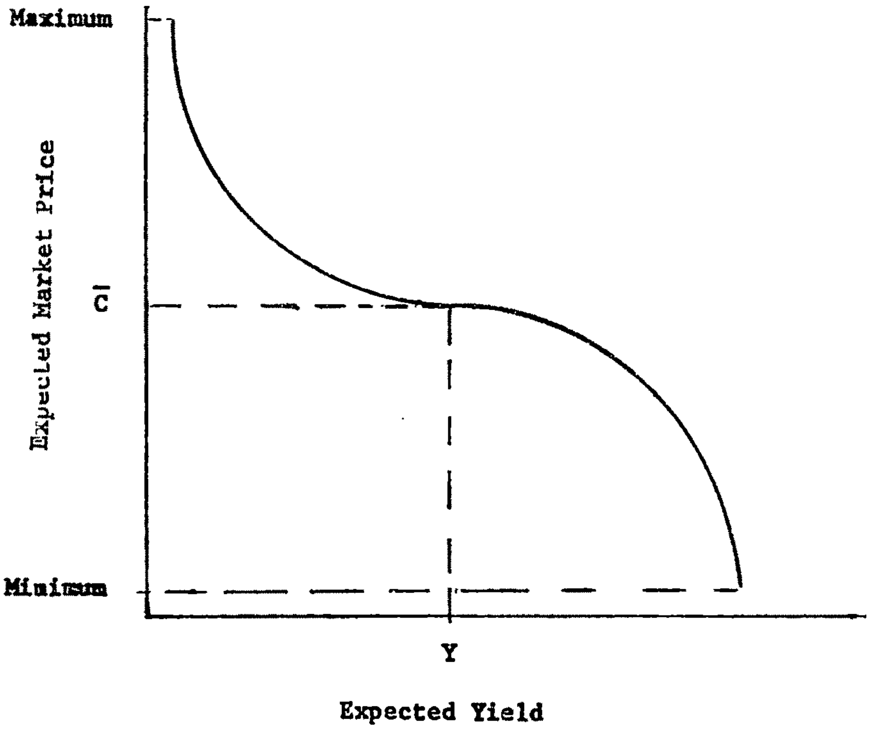

FIGURE 2. **Relationship between expected yield and expected market price**

able. Both of the variables treated here deal with expected values some time in the future. Moreover, while Y^* is the causative variable, the estimate of the expected cash price depends among other things upon the accuracy of the estimate of the expected yield. The farmer has—and probably feels this to be so to a greater degree than is justified—some control over the yield of his crop. Finally one would expect that logic would drive the farmer to the conclusion that he can predict yield better than prices and thus he has more confidence in his yield prediction. The net result of this reasoning is that one would expect the variance of the yield distribution from any given set of weather-technological-miscellaneous conditions to be smaller than the variance of the expected cash price distribution. This means that each expected cash price out of the range of all possible expected cash prices will be held with less certainty than the corresponding yield forecast that has generated it. Accordingly, a large change in the expected yield causes the change in the expected price to be held with more certainty than a small change in Y^* would. In the aggregate then, even if the $C-Y^*$ relationship for each farmer is linear, the result would be the one shown in Figure 2.

It can be shown that even if the $C-Y^*$ relationship is one of decreasing slope, the elasticity may increase over certain ranges as the yield increases, but this is not necessary. As seen in Figure 1, an increase in yield reduces the elasticity required for neutrality. Thus, as long as the actual elasticity falls less than the required (for neutrality) elasticity, the program will still be salutary.

Summing up, then: In view of (1) the low elasticity required for neutrality, even when the yield ratio is as great as unity; (2) the decrease in required elasticity as Y^* increases; and (3) the phenomenon of increasing actual elasticity with increasing expected yield; one can infer that this program is salutary.

The program is not symmetrical, however, when the expected yield falls, first, because this raises the yield ratio and therefore raises the elasticity required for neutrality (see Figure 1), and second, because the elasticity results are the reverse of those applicable to the case of increasing expected yields. For a linear $C-Y^*$ relationship, the experienced elasticity falls with decreasing expected yield. When the slope decreases as the expected yield falls, the experienced elasticity falls even more. The implications, therefore, are ambiguous; the program may or may not be perverse because the elasticity required for neutrality is rising while that actually experienced is falling.

What would result from the assumptions of the previous "most favorable" case? This relationship, in Figure 2, would be the most logical one to support for falling yields as well as for increasing expected yields. Thus, the $C-Y^*$ relationship would have an inflection point as $\bar{C}$, the normal expected price corresponding to Y, the normal yield. As yield falls or rises, price changes in the opposite direction at an increasing rate, until it hits either of two boundaries: (1) the "maximum" price, above which demand for the product falls to zero as substitutes are used to the exclusion of the given product; and (2) the "minimum" price, set by the cost of production.

This turns out to be the most favorable case here as well. While the elasticity for this curve may stay constant or even fall, it can also increase. While there is no *a priori* reasoning that would ensure rising elasticity with decreasing expected yields, the fact is that it could occur here while it is ruled out in the other two curvatures.

We are thus left in an inconclusive position.[20] When yields fall below "normal," the program may be perverse. Farmers may find it profitable to plant less when increased plantings are in order, to keep output constant or in line with consumption. When the expected yield increased, it was thought that profit maximizing considerations would lead to less planting. This was called a salutary effect of the program. Yet we must remember that this program emanates from agricultural surplus. When starting from minimal or normal stocks, it might be perverse for plantings to decrease in lean years; but any decrease in planting can be thought of only as salutary when staggeringly large surpluses exist.

---

[20] That is, the program does not permit a more definitive statement at this point.

The 1964 Data

The data of the 1964 program do not contradict the analytical conclusions of the previous section. As shown in Table 2, 35% of all wheat farmers became full participators and received 76% of the United States wheat allotment. The actual diversion amounted to 13.2%, slightly in excess of the 11.11% mandatory or qualifying diversion rate. North Dakota had the lowest diversion rate, 11.46%; South Carolina, the highest, 55.29%.

Table 2. Selected statistics of 1964 wheat diversion program

	U.S. total	Participating in 1964 program	Percent of U.S. total
Wheat farms (number)	1,730,186	611,728	35
Wheat allotment (acres)	53,271,718	40,682,419	76
Diversion			
Qualifying minimum (acres)		4,519,817	11.11
Total diversion (acres)		5,349,376	13.2
"Voluntary" diversion (acres)		829,559	

Source: [7, May 24, 1964].

Table 3 presents some of the details for the 15 largest wheat planting states, all with allotments greater than one million acres. These states accounted for 88.2% of the total national allotment and 91.8% of all the allotted acreage of participating farmers. It is misleading to compare these states' average participation rate of 79.8% with the national rate of 76%, since their share in the total allotment was so large. All the other states enrolled only 3.3552 of their 6.2478 million allotted acres, a participation rate of 53.7%. On the whole, the program was effective: four out of five acres represented participation in the important areas; only one of two elsewhere.[21] The 15 selected states diverted about 13% of their allotment, somewhat more than the minimum 11.11%. The balance of the states averaged 18.6% (.6248 diversion on 3.3552 million allotted acres). This implies that

---

[21] If these selected states had been restricted to the largest 9, rather than 15, Idaho would have been the only nonsoft red wheat state excluded. The five predominantly soft red wheat states of Illinois, Indiana, Michigan, Missouri and Ohio enrolled 2.5200 out of 7.2626 million allotted acres. Their participation rate was 34.6%. This raised the 9 other states' rate to 87.5% and lowered the other states' rate to 45.0%. At this time, however, the surplus problem was in hard winter and spring wheat and not in the soft red winter variety. Therefore, the conclusion that this program was effective is not altered.

Table 3. Fifteen largest wheat states—selected statistics of 1964 program allotment

Source: [9, July, 1964, p. 42].

those farmers who found program participation profitable also limited their acreage enrollment to the (neighborhood of the) mandatory minimum. This is consistent with the *a priori* analysis: profit maximizing considerations would lead farmers to divert only the minimum required for participation in the program.[22]

A scatter diagram, showing the acreage allotment per signed farm (state average basis) and the diversion rate, is presented in Figure 3. The diversion rate, the magnitude of which we are trying to explain, is in terms of units, each of which is 11.11% of the allotment. The minimum value this variable can take on is, of course, one. South Carolina has the highest diversion rate, 4.98, which means that these farmers, on the average, diverted almost five times as much acreage as was necessary to qualify for participation.

The fifteen largest states of Table 3 were ranked with respect to both of these variables. Kendall's coefficient of rank correlation is .619. The *t* test yields a value of 3.17. Since this value would occur less than 1 time out of

---

[22] That the 5 largest soft red winter wheat states had low participation rates is also consonant with this reasoning. The break-even criterion decreases as the expected cash price increases. With this variety in relative scarce supply, the expected cash price would rise and thus make participation less profitable.

100 if chance alone were operative, the null hypothesis—that there is no relation between size and diversion rates—may be rejected.

The simple regression for the five soft wheat states of Table 3 is

$$\text{Diversion Units} = 3.212 - \underset{(.047)}{.141}\ \frac{A}{SF}, \qquad \bar{r}^2 = .67.$$

This indicates that for every acre that the allotment on a per signed farm basis increases, A/SF, the diversion, decreases by .141 units, or 1.57% of the allotment. Average allotment per signed farm explains two-thirds of the variance of the diversion rate.

Use of a reciprocal transformation on the size variable in the scatter of Figure 3 results in the regression,[23]

$$\text{Diversion Units} = .844 + \underset{(2.017)}{22.976}\ 1/(A/SF), \qquad \bar{r}^2 = .762.$$

In the neighborhood of 120 acres of allotment per signed farm, the slope is −.00102. An increase in the allotment decreases diversion by only .00102 units, or .011% of the allotment. When the size of the average signed farm is 30 acres, however, diversion increases by .0255 units, or .283% of the allotment for every decrease of one acre in the allotment. For 20 acres, the respective changes are .0574 and .683%.

Clearly, variability in size is more important in explaining the diversion rate of small farms than of large farms. Almost one half of the states—20 of the 41 included in the study—averaged more than 30 acres of allotment per signer. Of these, 17 states had diversion rates less than 1½ units, and 13 states, less than 1¼ units; yet participators' acreage allotments ranged from 30 to over 300 acres.

As previously stated, these data are consistent with the analysis. The scatter of Figure 3 and the regression equations indicate that the larger the farm, the closer is the reaction to the theoretical optimum. It may be that small farmers are not as adept at profit maximization as larger farmers. It is possible, however, that the cost reduction on small farms is more significant than on larger farms. Moreover, since farmers with an allotment of less than 15 acres were permitted to divert it in its entirety, the assumption of equation (10), would not hold for these farmers.

Conclusion

It appears that despite the vastly diverse climatological and market conditions surrounding the production of the various wheat classes in the U.S.,

---

[23] This is based upon only 41 of the 44 states; Florida, Maine and Massachusetts were excluded because of unavailable data on other variables used in alternate regressions (none of which offered much more than that presented here).

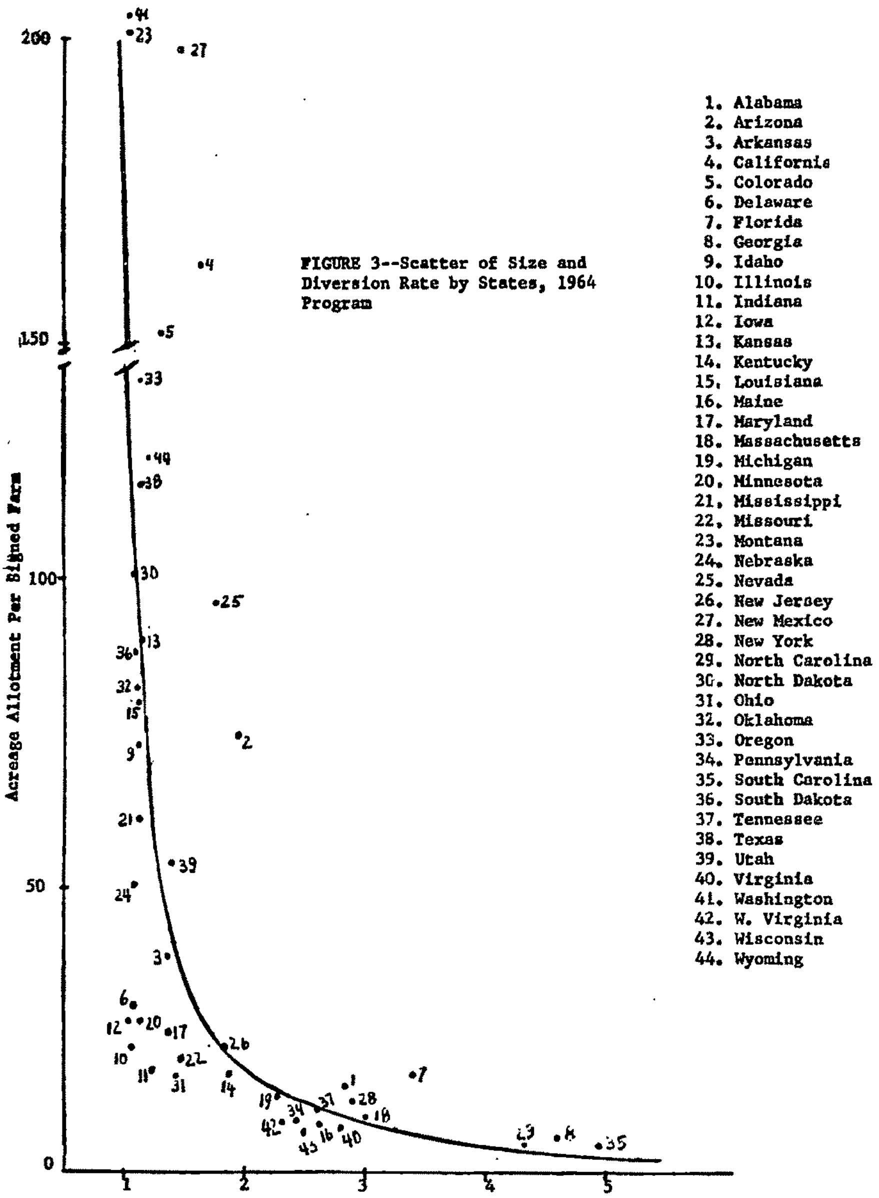

FIGURE 3--Scatter of Size and Diversion Rate by States, 1964 Program

it is possible, through the use of profit maximizing criteria, to approximate the reactions of "wheat farmers" to specific program proposals. In the light of this analysis, it seems that the voluntary program was efficacious in achieving the aims of freedom of choice and acreage reduction. It is clear, however, that additional voluntary diversion should not have been expected.

Econometric Study of Monthly Consumption Expenditures in Rural Uttar Pradesh*

SURESH D. TENDULKAR

This study presents some evidence of monthly consumption functions in the rural areas of the North Indian State of Uttar Pradesh. Since this region constitutes one of the largest and least monetized in India, attention is specifically focused on the cash and kind (or non-cash) components of (a) expenditure on food articles and (b) total consumption expenditure. Dynamic demand functions of a stock-flow variety are obtained for these broad groups. It is shown that cash outlays act as an inventory-adjustment mechanism whereas non-cash expenditure indicates a habit formation process. This behavioral difference of rural households with respect to cash and non-cash components of consumption expenditure has not yet been demonstrated and is regarded as one of the major results of this paper. With the use of a stock-flow adjustment system, numerical estimates of the instantaneous and steady-state equilibrium elasticities are derived with respect to total expenditure (a proxy for income) and prices.

THE main feature of a rural household economy is the integration of two decision units into one; viz., a family acts both as an entrepreneurial agent cultivating the land with hired and family labor and as a consumer unit determining the pattern of consumption expenditures. The production decision may be assumed to depend on the previous year's harvest and input prices, exogenous variables such as rains and weather, the input-output coefficients, and labor and capital availability. The consumption decision, on the other hand, is governed by behavioral considerations, ruling market prices, and income (in cash or kind) earned from production.

The purpose of this paper is to study a specific phenomenon emerging from the dual role of a rural household: the behavioral decision related to the consumption out of one's own produce or expenditure in kind (also referred to as "non-cash" expenditure) and expenditure in cash. The quantitative importance of this phenomenon in a predominantly rural, semi-monetized, developing economy needs no special emphasis.

The analysis begins with construction of a theoretical model of consumer behavior, with modifications appropriate for the peculiarities of semi-monetized agricultural consumer units, and continues with an exploration of some qualitative implications regarding the effects of prices.[1] Next, a

Behrman for detailed comments and suggestions.

[1] A really full-fledged general theory of a rural household economy will have to explain

SURESH D. TENDULKAR *is with the Planning Unit of the Indian Statistical Institute, New Delhi, India.*

brief outline is given of dynamic demand functions of a stock-flow character, and their steady-state properties are analyzed. This is followed by a description of data and variables used and a discussion of empirical findings. In a concluding section, the major results and some limitations of this study are summarized.

Slutsky-Hicks Theory Adapted to Rural Households

Imagine a household with stocks of agricultural commodities, faced with a decision of how much to sell and how much to retain for self-consumption, given the prices ruling in the market. It will maximize the utility function

$$u(q_1, q_2, \cdots, q_n) \tag{1}$$

subject to a budget constraint

$$\sum_{i=1}^{n} p_i(\bar{q}_i - q_i) = 0 \tag{2}$$

where q_i is the amount of the i^{th} commodity consumed, $\bar{q}_i$ is the stock of the i^{th} commodity with which the household enters the market, and p_i is the market price. The cash in hand is assumed to be negligible.

The familiar necessary conditions for equilibrium are:

$$u_i - \Omega p_i = 0 \qquad (i = 1, 2, \cdots, n) \tag{3}$$

where $u_i = \partial u/\partial q_i$ and these n conditions along with (2) determine the $(n+1)$ variables $q_1, q_2, \ldots, q_n$ and Ω, the marginal utility of income. Defining $u_{ij} = \partial^2 u/\partial q_i \partial q_j$, the second order conditions are given by

$$\begin{vmatrix} 0 & u_1 & u_2 \\ u_1 & u_{11} & u_{12} \\ u_2 & u_{21} & u_{22} \end{vmatrix} > 0, \quad \begin{vmatrix} 0 & u_1 & u_2 & u_3 \\ u_1 & u_{11} & u_{12} & u_{13} \\ u_2 & u_{21} & u_{22} & u_{23} \\ u_3 & u_{31} & u_{32} & u_{33} \end{vmatrix} < 0, \cdots,$$

$$(-1)^n \begin{vmatrix} 0 & u_1 & u_2 & \cdots & u_n \\ u_1 & u_{11} & u_{12} & \cdots & u_{1n} \\ \cdot & \cdot & \cdot & \cdot & \cdot \\ u_n & u_{n1} & u_{n2} & \cdots & u_{nn} \end{vmatrix} > 0$$

If we denote the last Hessian by U and the cofactor by a capital letter with the same subscripts as the corresponding element, we get, by differentiating equilibrium conditions (2) and (3) with respect to $\bar{q}_i$,

---

simultaneously the interdependent decisions related to the entrepreneurial and organizational factors on the one hand and behavioral responses regarding consumption expenditures on the other, in a general equilibrium framework. Our purpose is not so ambitious, however, both because of theoretical complexities and the lack of time-series data on all the relevant variables.

$$\frac{\partial q_j}{\partial \bar{q}_i} = p_i \cdot \Omega \cdot \frac{U_j}{U} \qquad (i, j = 1, 2, \cdots, n) \tag{4}$$

The partial income effect thus explicitly depends on the price of the commodity whose stocks are varied. The Slutsky equation is given by

$$\frac{\partial q_j}{\partial p_i} = \frac{(\bar{q}_i - q_i)}{p_i} \cdot \frac{\partial q_j}{\partial \bar{q}_i} + x_{ji} \qquad (i, j = 1, 2, \cdots, n) \tag{5}$$

where x_{ji} denotes the substitution term involving rates of change of marginal utilities. Defining the elasticities

$$\begin{aligned} \eta_{ji}^{p} &= \frac{p_i}{q_j} \cdot \frac{\partial q_j}{\partial p_i} = \frac{\partial \log q_j}{\partial \log p_i} \\ \eta_{ji}^{\mu} &= \frac{\bar{q}_i}{q_j} \cdot \frac{\partial q_j}{\partial \bar{q}_i} = \frac{\partial \log q_j}{\partial \log \bar{q}_i} \\ \bar{x}_{ji} &= \frac{p_i}{q_j} x_{ji} \end{aligned} \tag{6}$$

(5) may be written in elasticity terms as

$$\eta_{ji}^{p} = \left[1 - \frac{q_j}{\bar{q}_i} \right] \eta_{ji}^{\mu} + \bar{x}_{ji} \qquad (i, j = 1, 2, \cdots, n) \tag{6a}$$

and

$$\eta_{ii}^{p} = \left[1 - \frac{q_i}{\bar{q}_i} \right] \eta_{ii}^{\mu} + \bar{x}_{ii} \qquad (i, j = 1, 2, \cdots, n) \tag{6b}$$

Note that $\eta_{ii}^{\mu} > 0$ unless a commodity is an inferior good. The sign of the first term on the right depends on $(1 - q_i/\bar{q}_i)$. If for any given $\eta_{ii}^{\mu} > 0$ the household ends up consuming more of the i^{th} commodity than the stock with which it starts, the overall income-effect will be negative, thereby strengthening the gross-substitution effect. On the other hand, if $q_i < \bar{q}_i$, the price elasticity would turn out to be less than the pure substitution effect. The intermediate case $q_i = \bar{q}_i$ results in equality between gross and pure substitution effects. There also arises a possibility of a strong income effect dominating a pure substitution term, thereby yielding a "perverse" gross-own-price-elasticity. The actual occurrence of these possibilities would obviously depend on the levels of initial stocks of different crops and their substitution elasticities in consumption.

Modifications

So far we have been dealing with essentially a classical theory of household behavior analyzed by Hicks [1]. Additional restrictions must be added to the model to take into account some peculiar features of an agricultural economy.

In the first place, if households happen to be below or near subsistence level, the analytical effects of rigidities introduced become uncertain. For example, there may be some minimal requirements of bare necessities to be consumed, whatever the income and price situation. Defining S to be a set of bare subsistence commodities, if for any $i \epsilon S$ the minimal $q_i > \bar{q}_i$, the other commodities q_j where $j \notin S$ may be sold in order to acquire these subsistence quantities, whatever the price situation. In fact, they may be sold in *higher* quantities in situations where (a) the minimal required $q_i > \bar{q}_i$, (b) the prices of commodities $i \epsilon S$ are going up, and (c) the prices of commodities $j \notin S$ are declining. In such cases, we get what are widely described as backward-bending marketed supply curves. The phenomenon is also exhibited for $i \epsilon S$ when the complement of S is empty and cash requirements remain fixed in nature so that when prices received increase, *less* will be sold to the market. The case in which large income effect exceeded the substitution effect, already noted, would create the same situation. These possibilities, however, have to be posed as empirical questions and no *a priori* treatment can be given to them in judging a collective behavior in a given situation.

Secondly, the quantities $\bar{q}_i$ may be understood in a *net* sense, after allowing for seed requirements and non-consumption payments such as rent and debt charges. However, if a farmer is at or below the subsistence level, he may choose to eat the seeds rather than make any non-consumption payments. In addition, $\bar{q}_i$ may also be taken to subsume income received in kind from hired-out labor services and other secondary sources of livelihood.[2]

A final major modification relates to the introduction of prices. The rural retail price indices alone are not sufficient predictors when a basic unit acts as both producer and consumer of the commodities and must decide how much to sell and how much to consume. Under these conditions, the parity index becomes theoretically relevant. The parity index is given by a ratio of the index of wholesle or harvest prices received by farmers to the index of retail prices of non-agricultural commodities paid by them. It indicates the terms of trade of the agriculturists and introduces three effects: (1) an income effect—since prices received by a farmer directly affect his real income level; (2) an own-price-gross-substitution effect in consumption—since prices received by a farmer in most cases refer to those commodities which his household also consumes; and (3) the effect of prices of substitutes and complements upon the composition of the expenditure group under consideration—induced by the component in the denominator, viz., the retail price index of nonagricultural commodities. Both the rural retail price index and the parity index have been introduced into our empirical analysis as alternative explanatory variables. It is therefore appropriate to explore their qualitative implications with reference to some broad expenditure groups considered in our later econometric investigations.

---

[2] The author is indebted to J. R. Behrman for these suggestions.

Some Qualitative Deductions Regarding Price Effects

Since food articles account for about three-fourths of the total consumer expenditure in rural areas, we begin by examining the qualitative effects of the retail food prices (p_f) and the parity index (p) upon this group, denoted by q_f, and further subdivided into cash and non-cash components, denoted respectively by q_f^c and q_f^{nc}. Note that q_f^c contains on-farm produced as well as certain off-farm produced commodities, whereas the latter subgroup includes mainly on farm produced goods and perhaps a small part acquired through barter.

With regard to the normal effects of the Retail Food Price Index,

$$\frac{\partial q_f^c}{\partial p_f} < 0; \qquad \frac{\partial q_f^{nc}}{\partial p_f} < 0; \qquad \frac{\partial q_f}{\partial p_f} < 0$$

since p_f catches the usual own-price effect, the important qualification being that the income effects[3] do not overwhelm pure substitution effects. If the last statement does not hold, the signs would be reversed.

As to the effect of the parity index, it may be observed that

$$\frac{\partial q_f}{\partial p} = \frac{1}{\dfrac{\partial p}{\partial q_f}} \tag{7}$$

This is justified because two functions involved are $q_f = \phi(E,p)$ and $p = \psi(E,q_f)$ which may be assumed to be single-valued and the same expenditure level is held constant in both cases. Equation (7) can be expressed further as

$$\frac{\partial q_f}{\partial p} = \frac{1}{\dfrac{\dfrac{1}{p_n}}{\dfrac{\partial q_f}{\partial p_r}} - \dfrac{p_r}{p_n} \cdot \dfrac{\dfrac{1}{p_n}}{\dfrac{\partial q_f}{\partial p_n}}} \tag{8}$$

where p_r is the index of prices received and p_n the index of prices paid by farmers. Is it possible to assess *a priori*, the directions of $\partial q_f/\partial p_r$ and $\partial q_f/\partial p_n$ and hence of $\partial q_f/\partial p$? Taking into consideration the set P of produced and N of non-produced commodities in a consumer basket indicating the areas of applicability of p_r and p_n, several cases may be distinguished, depending upon the composition of the expenditure group:

---

[3] Income-effect in this context, as well as in later discussions, is to be interpreted as a composite entity resulting from $\{(1 - q_i/\bar{q}_i)\eta^u_{ii}\}$ in equation 6 (b).

(a) q_f^c belongs entirely or mainly to set P, so that commodities in this group would be substitutes for or are identical with those produced by a farmer. But these are also the goods whose rise in prices leads to increased incomes for him. Consequently, if the income effect of prices received is weaker than the pure substitution effect, $\partial q_f^c/\partial p_r < 0$; otherwise, $\partial q_f^c/\partial p_r > 0$. If the non-agricultural commodities whose prices are changing act as substitutes for those in the group, $\partial q_f^c/\partial p_r > 0$; if complements, $\partial q_f^c/\partial_{p_n} < 0$. The last case appears unlikely when broad groups are considered.

(b) q_f^c belongs entirely or mainly to set N. If commodities in this group are substitutes for those in set P, $\partial q_f^c/\partial p_r > 0$; if complements, $\partial q_f^c/\partial p_r < 0$, the magnitude being determined by the income effect of changes in prices received. $\partial q_f^c/\partial p_n \gtrless 0$ depending on whether income effect does or does not dominate the pure substitution effect.

(c) q_f^{nc} would belong mainly to P, therefore, $\partial q_f^{nc}/\partial p_r \gtrless 0$, depending again upon the relative magnitudes of income and substitution effects; whereas $\partial q_f^{nc}/\partial p_n \gtrless 0$, according as commodities in set N act as substitutes for or complements to those in the group.

The prospect of determining *a priori*, the direction of $\partial q_f/\partial p$ thus appears bleak. If, however, we assume that there is no close relation between p_n and p_r, we can narrow down the possibilities by using the following relationships:

$$\begin{aligned} \frac{\partial q_f}{\partial p_r} &= \frac{\partial q_f}{\partial p}\cdot\frac{\partial p}{\partial p_r} = \frac{\partial q_f}{\partial p}\cdot\frac{1}{p_n} \\ \frac{\partial q_r}{\partial p_n} &= \frac{\partial q_f}{\partial p}\cdot\frac{\partial p}{\partial p_n} = -\frac{\partial q_f}{\partial p}\cdot\frac{p_r}{(p_n)^2} \end{aligned} \tag{9}$$

so that it is clear that $\partial q_f/\partial p_r$ and $\partial q_f/\partial p_n$ will have opposite signs. Hence, although *a priori* it is not possible to find out the direction of change, it may be equally interesting, *once* the direction of the slope, $\partial q_f/\partial p$ is known empirically, to infer about the relative importance of the income and substitution effects as well as substitute-complement relationships between the various groups.

The same considerations apply to the effects of parity price index on the cash and non-cash components (q_c and q_{nc}) of total expenditure, with the additional specific notation that cash expenditures now also include off-farm produced food, non-food, and non-agricultural commodities. Since broad groups are under consideration, the composition of the cash component may conform more closely to that of the price index p_n; therefore, as long as substitution effect dominates (i.e., $\partial q_c/\partial p_n < 0$ and hence, $\partial q_c/\partial p_r > 0$), there is a possibility of getting a positive slope $\partial q_c/\partial p$. The complement of this group may then be expected to have a negative direction with reference to the same parity index.

Analytical Model

The analytical model employed in this paper is the dynamic demand function of the stock-flow variety formulated in continuous time. It was suggested by Houthakker [2] and presented in detail with empirical applications by Houthakker and Taylor [3]. A brief outline is presented here.

Assuming that demand for each good is influenced by one state variable and two flow variables, the following linear relationship is postulated:

$$q(t) = \alpha + \beta s(t) + \gamma x(t) + \lambda p(t) \qquad (10)$$

where $q(t)$ and $x(t)$ are instantaneous flows of consumption and income, respectively; $p(t)$ is price; and $s(t)$ is the level of the state variable at t. α, β, γ, and λ are parameters. The direction of β determines whether $q(t)$ is subject to inventory adjustment ($\beta < 0$) or habit formation ($\beta > 0$).

The generally unobservable state variable can be eliminated by using the relationship:

$$\dot{s}(t) = q(t) - \delta s(t) \qquad (11)$$

were $\dot{s}(t)$ denotes derivative of s with respect to time and δ is a depreciation rate assumed as a constant proportion of the level of the state variable. It has a conventional interpretation in the case of an inventory-adjustment process, whereas, for commodities subject to habit formation, it is taken to measure the speed at which the habit wears off.

By using a finite linear approximation to continuous time, it can be shown that the final estimation equation is:

$$q_t = A_0 + A_1 q_{t-1} + A_2 \Delta x_t + A_3 x_{t-1} + A_4 \Delta p_t + A_5 p_{t-1} + \nu_t \qquad (12)$$

where $A_0, \ldots, A_5$ may be shown to be simple functions of the structural parameters and ν_t is the error term.[4] This is referred to as the Standard Dynamic Model in this paper. The overidentification of δ when both prices and incomes are used as predictors can be handled by an iterative procedure. (For further details, see [3] pp. 8–25.)

In the structural equation (1), γ and λ denote short-term income and price derivatives when state variable is held fixed. However, when stocks are permitted to adjust so that $\dot{s}(t) = 0$, we get from (10) and (11) after rearrangement:

---

[4] The structure of this term is investigated in detail in [3], pp. 20–21 and 40–42.

$$\hat{q} = \left[\frac{\alpha\delta}{\delta - \beta}\right] + \left[\frac{\gamma\delta}{\delta - \beta}\right]\hat{x} + \left[\frac{\lambda\delta}{\delta - \beta}\right]\hat{p} \tag{13}$$

where "hats" denote steady-state variables. This gives static limit of the dynamic model with long-run derivatives given by $\gamma' = \gamma(\delta/\delta - \beta)$ and $\lambda' = \lambda(\delta/\delta - \beta)$. Observe that so long as $|\delta| > |\beta|$, with inventory adjustment process ($\beta < 0$), $\gamma' < \gamma$, implying that the initial response to change in income is larger than the long-run effect. On the other hand, in the habit formation case ($\beta > 0$), $\gamma' > \gamma$ because short-run impact is characterized by lethargy and inertia. Similar considerations apply to λ and λ'.

A special case of (12) that occurred in our empirical investigations may here be noted. In certain cases, the statistical difference $|A_2 - A_3|$ and $|A_4 - A_5|$ in equation (12) was found to be insignificant, implying $\delta = 2$, thus eliminating lagged income and prices and leaving current income and prices in the estimation equation. This equation takes the form

$$q_t = B_0 + B_1 q_{t-1} + B_2 x_t + B_3 p_t \tag{14}$$

which has the same form as the Koyck distributed lag equation. However, the interpretation of structural parameters differs from the Koyck formulation and is designated in this paper as the Distributed Lag Variant.

Before closing this section it may be emphasized that from the point of view of our present analysis, the dynamic model has two advantages: (1) it determines operationally whether any given commodity group is subject to an inventory-adjustment or habit-formation process; and (2) it enables us to study both the short-run and steady-state behavior of structural coefficients. It is thus an appropriate theory for bringing out the different impacts of the state variables and the underlying mechanisms of adjustment operating on different groups of expenditure. A somewhat unsatisfactory feature of the model,[5] as used here, is the lack of explicit grounding in utility function. However, the qualitative conclusions reached earlier would nevertheless be verified, since all of them involve observable phenomena in comparative static equilibrium situations. What we deduce from the dynamic demand functions presented in this section are the characteristics of two equilibrium situations: (1) an instantaneous equilibrium with the state variable held fixed and (2) a steady-state equilibrium when stocks are permitted to adjust. Consequently, in both cases, the stock-flow model may be expected to provide an empirical confirmation of the theoretical deductions previously formulated regarding the direction and implications of the price and income effects.

---

[5] This drawback has been removed from this theory by introducing a quadratic utility function involving state and flow variables. Preliminary findings are reported by Houthakker and Taylor [4].

The Data and Variables

The data used in this study have been drawn from a time-series of a changing and aggregated cross-section of over 1200 households surveyed monthly in the North Indian State of Uttar Pradesh.[6]

At a monthly level, the concept of a disposable income becomes nebulous and non-operational, especially in seasonal, semi-monetized, and self-employed occupations such as agriculture and related activities in rural areas. Consequently, total expenditure has been used as a surrogate for disposable income, since it is readily observed and more stable in the rural economy. Three price-series (all with the base 1957–58 = 100) have been used in the computations:

(1) The Rural Retail Price Index of food articles (p_f), which forms a part of the Rural Consumer Price Index;
(2) The parity index (p), representing the ratio of the agricultural wholesale prices received by farmers (p_r) to the Rural Retail Price Index of non-agricultural commodities (p_n) bought by them; and
(3) The Rural Wholesale Price Index of agricultural commodities (p_r).

The Rural Wholesale Price Index was used to deflate the total expenditure, its cash and non-cash components, and the Rural Retail Price Index of food articles which in its undeflated form was employed to reduce the expenditure on food articles, both cash and non-cash, to a constant price level.

Choice of Expenditure Groups

The empirical analysis has been carried out for the following broad groups of expenditures per household:

(i) Cash Expenditure on Food Articles (27%)
(ii) Non-cash (imputed) Expenditure on Food Articles (49%)
(iii) Total (Cash plus Non-cash) Expenditure on Food Articles (76%)
(iv) Cash Component of Total Expenditure (46%)
(v) Non-cash (imputed) Component of Total Expenditure (54%).

The figures in brackets indicate the percentage weight of the corresponding groups in the average total consumer expenditure over the six-year period, July 1957 to June 1963, covered by this study. Choice of broad groupings is governed by a practical consideration—that a stable consumption function at a monthly level is likely to exist for those groups of commodities that (a) are consumed frequently within a unit of time interval chosen and (b) form sizeable proportions of total outlays. It may be noted that our concern with cash and non-cash components (especially with reference to total expenditure) violates the generally accepted aggregation criterion of a within group homogeneity, based either on physical similarity of goods or similarity in satisfying a set of related wants. But it is justified if the consuming units treat cash and non-cash components differently with respect to their behavioral responses. That they in fact do so is one of the major findings of this paper.

---

[6] Per household value of consumption is published monthly for broad groups of expenditures on a regional basis and detailed for separate classes, such as cultivators, agricultural laborers, and others. The basic data have been collected from the various numbers of the *Monthly Bulletin of Statistics*, published by the Directorate of Economics and Statistics, Government of Uttar Pradesh, India. This study was carried out for the total of all classes and for the entire State of Uttar Pradesh. Anyone interested in details regarding sources, scope, and reliability of the data may obtain this information by writing directly to the author.

Seasonal Adjustment

With regard to the seasonal adjustment procedure, it should be noted that the seasonal influence is very important in models with time intervals smaller than a year. Several statistical techniques are available to eliminate seasonality (see, e.g., Kendall and Stuart [5], Chapter 46); but in most of these there is some degree of arbitrariness, while in some several observations may be lost. Recently, Klein, et al. [6], have suggested an introduction of seasonal dummies in a regression equation for seasonally unadjusted series to catch the effect of seasonality. Their procedure assumes that a seasonal factor works only as a shift factor on an intercept and does not affect regression slopes. In principle, seasonal effects on regression coefficient can also be permitted but the procedure becomes computationally complicated and the loss of degrees of freedom is considerable. In this study, eleven monthly dummy variables are used to represent each month (except June). The choice of the month left out does not affect the slopes and hence is immaterial (see Suits [9]).

Cash, Non-Cash and Total Expenditures on Food Articles

Table 1 presents the reduced form estimation equations for the standard dynamic model for cash, non-cash, and total expenditures on food articles (groups (i), (ii), and (iii), listed above) with three sets of predictors: (a) Total Expenditure, (b) Total Expenditure and Retail Food Price Index, (c) Total Expenditure and Parity Index. Statistically, the corrected squared multiple correlation increases as we move in each case from (i) to (ii) to (iii), as well as from (a) to (b) to (c). The Durbin-Watson statistic is either in an approximately doubtful range (for (a) (i), (b) (i) and (c) (i)) or shows no serial correlation, except 1 (c) (iii), where some evidence of negative correlation exists.[7] The equation I (c) (iii) is unsatisfactory statistically and

---

[7] As referees of this paper pointed out, it is not clear, in view of the Nerlove-Wallis paper [7], how much faith one should place in a Durban-Watson statistic when lagged endogeneous variables are included as explanatory variables. The problem of determining the existence of autocorrelation in such situations appears insurmountable. See also [3, pp. 40–42] in this connection.

[a] The structural coefficients and elasticities of the estimation equations are given in Table 2 identified by the same subscripts for the equation number as in this table.

[b] The coefficients of the seasonal dummies are not included for reasons of brevity. They may be made available on request.

[c] Figures in brackets denote the standard errors of the coefficients.

† Statistically insignificant (so regarded whenever any standard error exceeded the magnitude of the coefficients).

is presented only for the sake of completeness. Most of the important reduced form coefficients turn out to be statistically significant with expected directions. The structural estimates and elasticities of the equations corresponding to Table 1 are given in Table 2.

The conspicuous finding of Table 2 is the basic difference in the behavior of the households with respect to cash and non-cash expenditure on food articles. The cash component exhibits an inventory adjustment process with $\beta<0$, the immediate impact of increased expenditure being larger than the long-run effect when the stocks of these commodities are permitted to adjust. On the other hand, the non-cash imputed component follows a habit-formation process ($\beta>0$), the impact effect being sluggish and consequently smaller than in the steady-state situation. In the aggregate, food expenditure appears to be slightly habit-forming.

This basic difference is also reflected in marginal propensities and corresponding expenditure elasticities. The marginal propensity to spend cash on a food article lies in a reasonable range—between 0.27 and 0.33 in the short-run; between 0.16 and 0.20 in the long-run. The non-cash food expenditure containing the commodities produced as well as consumed by the farmers turns out to be sensitive to the effects of prices introduced and shows a broader range of marginal propensity to spend—between 0.09 and 0.22 in the short-run; between 0.34 and 0.48 in a steady-state.

For households whose cash outlay on food articles forms about 27 percent of the total, the short-run demand for these commodities may be expected to be more elastic than their demand for goods they themselves produce and consume. This is indeed brought out in our findings: the short-run expenditure elasticity estimates for the former range between 1.00 and 1.23; for the latter, between 0.19 and 0.45. In the long-run, the situation is reversed in cases (a) and (b), whereas the two estimates come fairly close to each other in (c). It is in explaining this phenomenon that the dynamic demand theory outlined earlier proves most useful and illuminating. We have observed that the cash and non-cash components of food expenditure are subject to different adjustment mechanisms which, acting in opposite directions, end up reversing the magnitudes of elasticities in a steady-state equilibrium. For cash outlays, the adjustment of stocks lowers the immediate impact effect in the long-run; whereas for non-cash expenditure, overcoming initial inertia raises the long-run effect considerably. In this connection, reference may be made to a similar empirical finding from budget studies by Sinha [8].

The introduction of Rural Retail Price Index of food articles (case (b)) consistently produces a negative-gross-substitution effect, thereby eliminating one of the sources of backward-bending supply curve; viz., the overwhelming income factor dominating the pure substitution term. The short- and long-term pure substitution effects show *a priori* directions. Cash out-

[a] The corresponding estimation equations of these relations are given in Table 1, identified by the same subscript for the equation number as in this table.

[b] Primed letters denote long-run steady-state coefficients.

[c] S.R. & L.R. indicate short-run and long-run, respectively.

[d] Substitution effect (denoted by "Subst." in the last two columns) is given by $(\eta_p{}^i + \alpha_i \eta_e{}^i)$ where $\eta_p{}^i$ and $\eta_e{}^i$ are elasticities with respect to price & total expenditure, respectively, evaluated at their respective means, and α_i denotes the proportion of the ith expenditure group in total expenditure.

lays on food show higher price elasticity than non-cash expenditure, in accordance with the expectations.

The parity index (case (c)) introduces the three influences previously noted. For both cash and non-cash purchases of food, the effects of changes in prices turn out to be statistically insignificant in the estimation equations 1(c) (i) and 1(c) (ii), yielding short-run price coefficients of somewhat doubtful value.[8] The long-run effect is positive for cash outlay. Based on equation (8), this implies that $\partial q_f{}^c/\partial p_r > 0$ and $\partial q_f{}^c/\partial p_n < 0$, and case (b) appears plausible. In other words, commodities in the cash outlay group are mainly off-farm produced agricultural goods. For non-cash food expenditures, a negative long-run price effect is exhibited which might have resulted from $\partial q_f{}^{nc}/\partial p_r < 0$ and $\partial q_f{}^{nc}/\partial p_n > 0$, indicating that the pure substitution effect of changes in prices received dominates the income term; commodities in this group act as substitutes for those in the non-agricultural group covered by p_n. There is thus a basic asymmetry in the effect of parity prices upon the two components of food expenditure.

Especially for the non-cash group, the coefficients in the reduced-form equations indicate a possibility that the statistical difference $|A_2 - A_3|$ and $|A_4 - A_5|$ may not be significant, thereby giving rise to a Distributed Lag Variant. The absolute differences and their standard errors in different equations are as follows:

	$\lvert A_2 - A_3 \rvert$	$\lvert A_4 - A_5 \rvert$
Equation 1(a)(ii)	0.0315	—
	(0.1140)	
Equation 1(b)(ii)	0.0153	0.0079
	(0.1503)	(0.2640)
Equation 1(c)(ii)	0.0523	0.0224
	(0.1179)	(0.1456)

Consequently, the value of δ was fixed *a priori* at 2.0, and the Distributed Lag Variant was estimated. The resulting estimation equations and corresponding structural estimates are presented in Tables 3 and 4, respectively. The corrected $\bar{R}^2$ goes up, and Durbin-Watson statistics remain

---

[8] Intuitively it seems obvious that if one or more reduced form coefficients are statistically insignificant, so would be estimates of structural coefficients. However, it need not necessarily be so. If a function involving reduced form coefficients is expanded in a Taylor series around a true structural parameter, neglecting second and higher order terms, the resulting expression would contain variances as well as covariances of reduced form estimates. A possibility then clearly arises that a structural coefficient may turn out to be statistically significant even though one or more reduced form estimates are not. Hence the use of a loose phrase in the text "of somewhat doubtful value." I am indebted to L. I. Taylor for pointing this out to me.

broadly unchanged. The current price term is significant in both equations 3(b) (ii) and 3 (c) (ii), implying that the dynamic effects in non-cash components operate directly through the lagged dependent variable and only indirectly through lagged prices and expenditure. This contrasts with the cash component where dynamic influences act directly through lagged cash outlays, lagged expenditures and prices, the first differences in total outlay, and price changes. When comparing the long-run expenditure elasticities in equations 2(a) (ii), 2(c) (ii), and 4(c) (ii), note that the addition of parity index lowers the estimate and makes it slightly *lower* than that for cash purchases (contrast equations 2(c) (i) and 4(c) (ii)). It thus appears that the explicit introduction of the forces of income effect, own-price-effect, and effects of prices of related goods, represented by the terms of trade index of agriculturists, yields a net expenditure elasticity lower, as expected, than that of retail food price or cash purchases. The overall pure substitution effect in equation 4(c)(ii) is positive and close to zero, implying that different influences of parity index seem to be mutually offsetting in nature. The fact that pure short- and long-run substitution effects in equation 2(c) (i) also are positive is no contradiction, since the cash plus non-cash food expenditures do not exhaust the total expenditure.

The conventional static linear, log-linear, semi-log, and inverse-semi-log forms of demand functions were also fitted to the data. It was found that in most cases dynamic equations perform better, and in a few cases do at least as well as the static forms, in terms of both corrected $\bar{R}^2$ and Durbin-Watson statistic.

Cash and Non-Cash Components of Total Expenditure

We now examine the behavioral relations connected with the cash and non-cash components of total consumption expenditure for which the parity index has been used as an appropriate overall price variable.

Tables 5 and 6 present the relevant estimation equations and structural coefficients, respectively. The corrected squared multiple correlation coefficient is statistically significant in all the equations. Moreover, in most cases, the reduced form coefficients exceed their standard errors by large multiples. A close scrutiny of the equation 5(e)(v) for non-cash expenditure indicates that $|A_2 - A_3| = 0.0089$ with a standard error of 0.1597 and $|A_4 - A_5| = 0.0087$ with a standard error of 0.2057. This suggested a Distributed Lag Variant whose estimated reduced form relation is denoted by 5(ē)(v) in Table 5.

The cash component, now including non-agricultural, non-food articles, such as clothing, footwear, and fuel and light, exhibits an inventory adjustment behavior, whereas the non-cash portion is habit forming in character. Due to omission of a price variable in the first two equations in Table 6, the mis-specification bias in the expenditure coefficient appears to be down-

ward for the cash component and upward for its complement. (Compare the estimates in equation 6(d)(iv) with 6(e)(iv) and in 6(d)(v) with 6(e)(v) and 6(ē)(v)). The marginal propensity to spend on cash purchases is very high at 0.73 in the short-run and 0.71 in a steady state situation; for non-cash expenditure, the corresponding short-run estimates are around 0.17 while long-term estimates range between 0.25 and 0.27. Only a slight difference is evident between the short- and long-run expenditure and price coefficients (equation 6(e)(iv)), indicating that the adjustment mechanism of the cash outlays works speedily. As previously conjectured, the asymmetrical impact of the parity index on cash and non-cash components is brought out in a sharper focus. The pure substutition effect is positive for cash purchases and negative for its complement, as we would expect in a mutually consistent consumer behavior. The expenditure elasticity in the short-run, as well as long-run, turns out to be higher for the cash component than for the non-cash group. Its numerical magnitude amounts to 1.50 (short-run) and 1.55 (long-run) for cash and ranges between 0.29 and 0.31 (short-run) and 0.47 to 0.49 (long-run) for non-cash outlays. The demand with respect to parity index tends to be inelastic for both the groups, although its impact is positive for cash purchases and negative for its complement. These findings are in line with *a priori* reasoning that, in the long run, the effects of increased incomes (expenditures) and improved terms of trade would be reflected in a rural household's expanding demand for non-produced non-agricultural commodities.

Conclusions

As far as the author is aware, this study represents the first attempt at econometric analysis of monthly rural consumption expenditures with an explicit introduction of expenditure and price effects. Dynamic demand functions of a stock-flow variety are shown to be appropriate for this purpose.

By focusing attention on cash and non-cash (imputed) outlays on broad groups of consumption, this paper shows for the first time behavioral differences of rural households with respect to these components. Cash purchases act as an inventory adjustment mechanism, while non-cash outlays exhibit a habit persistence process. This finding may have far-reaching policy implications in projecting rural consumer expenditures in a predominantly agricultural, semimonetized developing economy in the process of industrialization.

Theoretical considerations suggested that the parity index may be an appropriate factor in explaining the rural household's consumption behavior Consequently, the parity index was introduced in the demand functions as an alternative predictor and found to yield plausible results, especially with respect to its asymmetrical impact on cash and non-cash components. Its inclusion also led to confirmation of the oft-repeated statement regarding the favorable effect of expanding incomes and improved terms of trade of agriculturists on their increasing demand for non-produced, non-agricultural commodities in the process of development. The significance of this phenomenon is stressed continually in theories of economic development.

Finally, numerical estimates have been obtained for the expenditure and price elasticities of cash and non-cash components of (a) expenditure on food articles and (b) total consumption expenditure. The instantaneous short-run and the steady-state long-run equilibrium values have been deduced in each case. The importance of this empirical information in formulating long-range development plans needs no special justification.

With regard to the shortcomings of our analysis, it may be noted that some important influences acting on the consumer expenditure were omitted, such as size and age composition of the rural families, wealth and liquid assets, etc. Also omitted from consideration was the simultaneity in decision making on the production and the consumption side.[9] Most important, the justly famous limitations of a repetitive, multi-purpose survey carried out by official agencies among poorly literate rural people apply equally to the data used in this paper. However, if plausibility of results may be taken as a confirmation of the overall accuracy, the data appear to do reasonably well.

A Comparison of the Determinants of Wool Production in the Six Leading Producing Countries: 1949-1965*

WILLIAM H. WITHERELL

In this study, a general model of seasonal wool production is developed, based on the assumptions of (1) a lagged adjustment of actual to desired output, and (2) "naive" or "static" price expectations. The results of fitting this model to data from six major wool-producing countries for the seasons 1948-49 to 1964-65 indicate that wool production responds fairly weakly to economic factors and then only after a substantial lag. The estimates obtained of short- and long-run elasticities of wool production with respect to wool prices and the prices of the joint product, lamb, and the substitute products, wheat and beef, are all quite low. Australian wool production is found to be affected positively by fertilizer usage, and rainfall is found to be an important factor for wool production in Australia, South Africa and Argentina

WHILE some wool is produced in nearly every part of the world, the Southern Hemisphere countries of Australia, New Zealand, South Africa, Argentina, and Uruguay account for some 60 percent of the worlds' wool production, and Australia alone produces about 33 percent. It is the most important export of Australia, New Zealand and Uruguay. This paper describes an econometric analysis of the production of wool in the five countries mentioned, as well as in the United States, which produces about one-third of the wool it consumes. Seasonal data from 1948–1949 to 1964–1965 were used in the estimation. The study is part of a larger study of the world wool market [22] and was undertaken to provide production equations for an annual world wool market model. First, a theoretical model of the seasonal production of wool is described, followed by a discussion of the various data series used and some of the statistical problems faced in fitting the model to the time series data. Estimation results are then presented and compared for the six countries studied. Finally, some general conclusions are given about the nature of seasonal world wool production.

Constructing a General Model

Raw wool is obtained from the shearing of sheep, which have an average life of a little more than five years. The sheep are usually shorn first within

This paper is based on research conducted at the Econometric Research Program of Princeton University and made possible by a fellowship from the Textile Research Institute. The views expressed are solely those of the author.

WILLIAM H. WITHERELL *is a senior economic analyst for the Planning Coordination Department of Standard Oil Company (N.J.).*

one year after birth, and yearly thereafter. Because of the relatively fixed length of the production process and the importance of overhead costs,[1] the ability of wool producers to respond quickly to market expectations or actual market changes is quite limited, especially their ability to increase production. Short-run changes in the amount of wool produced may result from unfavorable weather conditions or an outbreak of disease. In many of the wool producing areas, lamb and mutton are important joint products; in these areas, producers are thought to base decisions as to the number of adult sheep and lambs to slaughter on the present and expected future relative prices of wool, lamb, and mutton.

In the longer run, wool producers make their production decisions by considering the relative expected returns of alternative uses of their resources—principally, growing cereal grains or raising cattle. However, a good proportion of the world's wool is produced in semi-arid and arid regions in which alternative uses of the producer's land may not exist; in such situations, the producer may have little economic choice, even in the long run, but to continue production even when market conditions become adverse. However, it should be noted here that in recent years, through the development and implementation of more advanced agricultural methods, specifically, the improvement of pastures by fertilization, seeding, and irrigation, and the control of diseases, predators, and competitors for the food supply, producers in the six countries under consideration have been able to increase significantly the yield per acre and per sheep of raw wool.

It was necessary to build into the wool production equations for each country the essential dynamic aspect that the level of a country's production of wool cannot be changed rapidly in response to changing economic conditions. This was accomplished by using the distributed lag model of supply adjustment developed by Nerlove in his studies of agricultural supply functions for the United States [13, 15, and 16]. In particular, letting Wj_t and Wj_{t-1} be the actual level of wool production in country j in seasons t and $t-1$, and Wj_t^*, the "desired" or "equilibrium" level of production in country j for season t, it is assumed that the change in actual production in season t over season $t-1$ is a fraction, B, of the desired or equilibrium increase. That is,

$$\text{(i)} \qquad Wj_t - Wj_{t-1} = B(Wj_t^* - Wj_{t-1})$$

The size of the fraction B, called the "coefficient of adjustment," is a measure of the speed with which actual production adjusts in response to factors determining desired production. This adjustment speed is determined by the biological production lag and by institutional, technological, and behavioral rigidities. Variations in rainfall and the use of fertilizer also are thought to affect this adjustment process; and when data on these factors were available for a country, the corresponding variables were added to (i) as additional linear terms.

---

[1] G. Blau [1, pp. 191–192] finds that 65% of total producer costs are either fixed (independent of the volume of production) or "semi-variable" (only partly dependent on the volume of production).

It is important to note that equation (i) is a difference equation and that solving for Wj_t yields

$$\text{(ii)} \qquad Wj_t = \sum_{i=0}^{\infty} B(1-B)^i \, Wj^*_{t-1}.$$

That is, actual production in season t is a distributed lag function of current and past desired or equilibrium levels of production.

The desired level of production for season t, Wj_t^*, is assumed to be a linear function of the expected prices for season t of wool, Pw_t^e, and of other substitute (or perhaps complementary) products, for example, lamb, Pl_t^e; that is,

$$\text{(iii)} \qquad Wj_t^* = a + bPw_t^e + cPl_t^e + u_t$$

where u_t is a stochastic term. With the exception of the equations for Argentina and Uruguay, the results given in this paper assume that there is a two year lag in the initial impact of production decisions on actual output, due to the inherent difficulties of rapidly adjusting to changes in the market outlook. When compared with alternative assumptions of one to five year lags, this assumption yields the most satisfactory empirical results (except for Argentina and Uruguay, where a one year lag appears to be more appropriate) and is consistent with the basic biological lag in wool production. Thus, the expected prices and the desired output in (iii) are assumed to be from the viewpoint of season $t-2$. The simple model of price expectations used in this study is that of "naive" or "static" expectations; that is, we assume

$$\text{(iv)} \qquad Pw_t^e = Pw_{t-2}.$$

The price expected for season t from the viewpoint of season $t-2$ is the actual price in season $t-2$. Other simple models of price expectation were tried, specifically, that of "extrapolative" expectations in which estimates of future prices are made by extrapolating the current price adjusted for the most recent change in prices, and models which assume that the expected price is a weighted average of past prices (various arbitrary weighting schemes were used). However, these alternative simple models did not yield as reasonable results as did the "naive" model. The testing of more complex expectations models would require longer and better data series than those used in this study.

With the assumption of "naive" expectations formed in season $t-2$, equation (iii) becomes

$$\text{(v)} \qquad Wj_t^* = a + bPw_{t-2} + cPl_{t-2} + u_t.$$

The final form of the equations estimated in this study is obtained by substituting equation (v) into equation (i), yielding

$$\text{(vi)} \qquad Wj_t = Ba + (1 - B)Wj_{t-1} + BbPw_{t-2} + BcPl_{t-2} + Bu_t,$$

which is a linear equation in observable variables.[2] If the stochastic term u_t is not serially correlated in (v), there will be no serial correlation in the stochastic term of (vi).

The specification given in (i) and (iii) illustrates the Marshallian distinction between short and long runs, the use of the term "long-run" here corresponding to Marshall's use of the term "normal" [9, pp. 378–379]. In the short-run, the supply of factors to the economic unit, for example, a wool ranch, is relatively fixed; while as longer and longer runs are considered, the supply of factors becomes more and more variable and more alternative courses of action become available. As Nerlove notes [14, p. 235], "Thus, from any point on a long-run supply schedule, we may think of a fan of short-run supply curves which gradually approach the long-run supply schedule from the right above it and from the left below it." Since there is no one distinct "short-run" supply curve, the choice of which short-run supply curve to estimate is rather arbitrary. In our case, the decision to look at the two year supply curves (except for Argentina and Uruguay) was based on the purposes of the study, the nature of the production process, and the statistical results obtained. Moreover, what is observed is not the long-run supply curve but, instead, since the situation is constantly changing, points on the various short-run curves corresponding to no one supply curve. However, if the specification of (i), (iii), and (iv) is correct, estimates of the long-run supply curve and of a "short-run" supply curve for each country can be derived from estimates of (vi). That is, estimates of the "short-run" (two year) elasticities of supply, with respect to the explanatory variables, are readily obtained by multiplying the respective coefficients in (vi) by the ratios of the mean values of the explanatory variables to the mean value of supply. Estimates of "long-run" or equilibrium elasticities corresponding to equation (iii) can then be calculated by dividing the estimated "short-run" elasticities by the estimated value of B.

It should be emphasized that these structural inferences from the coefficients of (vi) are based on our assumptions of a lagged adjustment of actual to desired supply and of the determination of desired supply by naive expectations of prices, these expectations formed in season $t-2$. For alternatively, equation (vi) could be interpreted as the reduced form equation of a model in which wool production is determined by geometrically declining distributed lag functions of the actual prices of wool and lamb, where the lags begin in season $t-2$ and where both distributed lags are identical, having the same geometric weight B. However, it would no longer follow that, if the stochastic terms were serially uncorrelated in the original model, they also would be uncorrelated in (vi). Noting the similarity of these models, Griliches [6, pp. 16–17 and 42–45] indicates that it is very difficult to discriminate between them on empirical grounds. An interesting alternative to the model used in this paper would be one in which the dependent variable is specified to be a function of *different* distributed lags in the explanatory variables. For example, Martin [10 and 11] has estimated demand equations in which the explanatory variables enter with different geometrically declining distributed lags. Such models, however, are considerably more difficult to estimate; and because of the limited number of observations available for this study, this alternative approach did not seem feasible.

---

[2] The author is not aware of any compelling reason to think that some specific non-linear form would be preferable. Yet, if the "true" structure is non-linear, equation (vi) may be considered to be a linear approximation of this structure; that is, the first terms in a Taylor's expansion of the non-linear form.

Data Considerations

Since wool production is seasonal (in most countries, from September to June), wool production and prices are expressed in seasonal terms in this study; and, where possible, so are the other variables used. The production data are expressed in terms of millions of pounds (clean basis);[3] and the price variable used is a weighted average of the seasonal averages of the Dominion wool price series for 64s and 46s (Bradford counts) wool, the weights being determined by the percentage of Merino and crossbred quality wool in the total wool clip. Thus, the price series is that of a composite quality wool. The Dominion wool price series are averaged weekly prices for the different qualities of wool and are compiled by the New Zealand Wool Commission on the basis of quotations from sales held during the week in the United Kingdom, Australia, New Zealand, and South Africa. These price series, quoted in terms of British currency, were converted to U. S. cents per pound (clean basis) at the then current exchange rate and then deflated by a seasonal index of world commodity prices, constructed by averaging the monthly Sauerbeck index of commodity prices from July to June. All other price series used are expressed similarly in terms of United States dollars. The price series for Australia, New Zealand, and South Africa were deflated by the Sauerbeck index of commodity prices; the prices for the United States, by the wholesale price index for farm products; and the prices for Argentina and Uruguay, by export price indices for these countries.

---

[3] When raw wool is shorn from sheep, it contains a large amount of grease and dirt. Wool prices and trade are in terms of the expected clean content of the raw wool, and hence we express wool production on a clean basis. The wool data are derived from applying conversion factors, developed by the Commonwealth Economic Committee, to grease basis wool production series that are published in [21].

Fluctuations in rainfall have had a significant effect on wool production in many parts of the world, particularly in Australia, South Africa, and Argentina, where the sheep raising areas are subject to periodic droughts. Seasonal rainfall indices were used to account for the importance of this factor. The Australian Bureau of Agricultural Economics has constructed such an index for Australia by weighting the seasonal rainfall index for each state by the *average* percentage of Australian sheep in each state over the period spanning the seasons 1947–48 to 1964–65. This approach was followed in constructing the indices for the other five countries.

The Estimation Methods Used

In all of the forms of equations describing the production of wool that are considered, any explanatory variables that are currently endogenous to the rest of the wool market are excluded. That is, in a world wool market model, these equations would be recursive to the rest of the system. Hence, there should be no problem of simultaneous equation bias, and the method of ordinary least squares was employed to obtain initial equation estimates. However, a basic assumption of this method is that there is no correlation between the disturbance terms of different periods; and this assumption is often violated in the analysis of economic time series. When this is so, ordinary least squares estimated may be inefficient [8, p. 179]. Moreover, if in addition a lagged value of the dependent variable is included as an explanatory variable, as is the case here, Griliches [5] has shown that the ordinary least squares estimate of the coefficient, (1-B), of this lagged dependent variable will be biased. Since the estimates of the "long-run" elasticities depend crucially on the estimate of B, so that a small error in the estimate of B could cause a substantial error in the estimates of the "long-run" elasticities, such elasticity estimates should not be considered very precise when obtained from equations for which the disturbances appear to be serially correlated. Unfortunately, while the Durbin-Watson statistic [4] was developed as a test of the hypothesis that the residuals are uncorrelated, the significance tables computed by Durbin and Watson are not valid for equations containing lagged forms of the dependent variable. Nevertheless, the values of this statistic were computed for the wool supply equations in order to provide a rough comparison of the degree of auto-correlation present in the residuals of these equations. In cases where this statistic appeared to be "unusually" high or low, the equations were re-estimated by an approximation to generalized least squares suggested by Cochrane and Orcutt [2] and discussed by Johnston [8, pp. 193–194 and 197–199].[4]

In this method, it is assumed that the residuals are generated by a simple Markov process. The data are transformed by estimates of the auto-correlation coefficients of the residuals, and new estimates of the equations are obtained by applying ordinary least squares to these transformed data. In this study, the estimates of the auto-correlation coefficients of the residuals were obtained by regressing the residuals of the initial ordinary least squares estimates of the equations on their lagged values. Thus, the resulting estimates of the auto-correlation coefficients are biased. If the assumption about the Markov scheme is correct and if reasonably good estimates of the auto-correlation coefficients are obtained, the residuals from the equations using the transformed data should be uncorrelated. This procedure can be done iteratively, assuming successively higher order Markov schemes, but one degree of freedom is lost at each step. Because the number of available observations was small, only first and second-order Markov schemes were considered; and for most cases, these simple schemes appear to be adequate.

---

[4] This approach is only one of a number of possible solutions to this problem. For other promising methods see [6] and the references cited therein.

Australian Wool Production

Australia produces about 33 percent of the world's wool, of which about 70 percent is Merino wool and 30 percent is crossbred wool. Wool production in Australia rose fairly steadily in the seventeen seasons studied, from 575.3 million pounds (clean basis) in 1948–49 to 1,031.5 million pounds (clean basis) in 1964–65. The major cause of this growth appears to have been the technological improvements made throughout that period—in particular, the increased use of superphosphate fertilizers on pastures and the control of rabbits by the planned spread of the disease, myxomatosis, and by poisoning. Fluctuations in rainfall are thought to be a major cause of year to year variations in Australian wool production, affecting both the size of the sheep population and the average fleece weight per sheep. The main economic factors appear to be the prices farmers receive for wool, lambs, and mutton, and for wheat, a major substitute crop in the large wheat-sheep areas of the country.

In the two versions of an Australian wool production equation given below—equations (1) and (2)—the dependent variable, Wau_t, is Australian wool production in season t, in millions of pounds (clean basis); and the explanatory variables are lagged wool production, Wau_{t-1}; the deflated world wool price in U. S. cents per pound for the season $t-2$, Pw_{t-2}; the deflated Australian wheat price in U. S. dollars per metric ton for the first calendar year of season $t-2$, Pwhau_{t-2}; the deflated Australian lamb price, in U. S. cents per pound for the first calendar year of season $t-2$, Plau_{t-2}; the use of super-phosphate fertilizers in thousands of metric tons in season $t-1$, Fau_{t-1}; and an Australian index of rainfall in season t, Rau_t.[5] Both equations were estimated by the Cochrane-Orcutt procedure, for the Durbin-Watson statistics for the ordinary least squares estimates of these equations indicated substantial negative serial correlation in the residuals. A first order Markov process was assumed to have generated the residuals.[6]

---

[5] The wheat price used is the Australian Wheat Board's export price for fair-average quality wheat, bulk basis, f.o.b. at ports, and the lamb price is the wholesale price, slaughter weight at Melbourne, for first and second quality lamb. These prices and the fertilizer usage series are published in [20].

$$\begin{aligned}(1)\qquad Wau_t = &\underset{(.160)}{.473Wau_{t-1}} + \underset{(.323)}{.518Pw_{t-2}} + \underset{(1.600)}{3.476Plau_{t-2}} \\ &- \underset{(1.074)}{1.748Pwhau_{t-2}} + \underset{(.199)}{.583Fau_{t-1}} + \underset{(.366)}{.138Rau_t}\end{aligned}$$

$$R^2 = .99, \quad s.e. = 23.23, \quad D.W. = 2.71, \quad B = .527, \quad p_1 = -.580$$

$$\begin{aligned}(2)\qquad Wau_t = &\underset{(.141)}{.695Wau_{t-1}} + \underset{(.399)}{.660Pw_{t-2}} - \underset{(1.360)}{1.749Pwhau_{t-2}} \\ &+ \underset{(.208)}{.381Fau_{t-1}} + \underset{(.387)}{.569Rau_t}\end{aligned}$$

$$R^2 = .96, \quad s.e. = 30.42, \quad D.W. = 2.40, \quad B = .305, \quad p_1 = -.417$$

The numbers in parentheses beneath the coefficients are their estimated standard errors. For each equation, R^2 is the coefficient of determination, s.e is the standard error of estimate, *D.W.* is the Durbin-Watson statistic, *B* is the estimate of the coefficient of adjustment (from equations (i) and (vi)), and p_1 is the estimated first order auto-correlation coefficient of the residuals of the *OLS* estimate of the equation.[7] For these equations, the Cochrane-Orcutt procedure appears to remove some of the negative autocorrelation in the residuals, although the problem still exists in these estimates.

Equation (1) contains the lamb price variable, while (2) does not. The rainfall index enters both equations, but its coefficient is much less significant in equation (1). Although one would suspect that this difficulty is caused, in part, by a problem of multi-collinearity with respect to the independent variables, it is interesting to note that the simple correlation between the rainfall index and the lamb price series is only +.17. While other forms of these equations were estimated, dropping or adding variables and changing the lags, this ambiguity still remained.

---

[6] The above equations do not contain constant terms because estimates obtained when a constant term was included resulted in intercepts not statistically different from zero, equations having worse statistical properties, and, in some cases, coefficients which contradicted rather firmly held *a priori* assumptions based on economic theory. Similar comments apply to the other equations in this study that lack constant terms.

[7] The high values of the R^2 statistics are not solely the result of including the lagged dependent variable. When equations (1) and (2) were estimated omitting the lagged dependent variable, the R^2 statistics were about .9 in both cases. The various elasticity estimates were also similar, lying between the short-run and the long-run estimates obtained here.

Equations (1) and (2) also differ with respect to the estimates of the coefficient of adjustment, B, that they yield, .527 from (1) and .305 from (2). Yet, both of these estimates indicate that the adjustment of actual to desired production levels in Australia is indeed incomplete after a lag of two years, for only one third to one half of the desired change occurs. Thus, the effects of changes in economic conditions and production are spread out over a number of years, as expected.

The "short-run" (two year) elasticities of supply to wool prices derived from (1) and (2) are quite low: +.066 and +.084, respectively. The latter estimate is very close to the two year price elasticity estimate of +.08 obtained by Dahlberg for the Wheat-Sheep Zone of South Australia for the period 1949–61 [3, p. 58]. The former estimate is close to the one year price elasticity estimate of +.0698 obtained by Powell and Gruen in their study of the Australian crop/pastoral complex covering the seasons 1947–48 to 1964–65 [18, p. 78; see also 17 and 19]. However, because of differences in the models and data series used in these studies, the resulting estimates are not strictly comparable with ours. The estimates of the "long-run" or equilibrium price elasticity of supply derived from (1) and (2) are +.125 and +.276, respectively, which seem to be quite low. However, such estimates depend crucially on the possibly biased estimates of the coefficient of adjustment and should be considered to be considerably less precise than the estimates of the short-run elasticity.

The lagged price of wheat, a major alternative crop in many sheep raising areas of Australia, enters with a similar negative coefficient in both equations, though the wheat price coefficient is less significant in equation (2). The short-run cross-elasticities of supply with respect to wheat prices obtained from the two equations are −.0456 and −.0457, respectively; and the corresponding long-run elasticities are −.087 and −.150. In comparison, Dahlberg [3, p. 58] obtained an estimate of −.42, indicating that a considerably stronger substitution effect between wool and wheat prices exists in the Wheat-Sheep Zone than in the country as a whole. This is to be expected, for it is in this region that most of the wheat is grown. Powell and Gruen [18, p. 78] obtained an estimate of the one year cross-elasticity of wool supply with respect to wheat prices of −.0521, which is much closer to our estimate.

The lamb price variable enters equation (1) with a significant positive coefficient, which would indicate that high lamb prices encourage the raising of more lambs, that is, the creation of larger flocks, rather than having the effect of decreasing sheep numbers as producers attempt to reap short-run profits from the then current high lamb prices. This result is quite reasonable, if the producers assume future lamb prices will be high when the current price is high. To slaughter more lambs would be to disinvest in lambs just when the expected future returns from lamb production rises. Yet, to an increasingly important extent, fat lambs are a specific product in Australia, usually being bred from an English-type breed of ram on cross-bred ewes. Since this type of lamb is unsuited for wool production, there is little chance that these lambs will avoid the slaughter house. However, the cross-bred ewes are dual-purpose animals, and in periods of high lamb prices, there may be less culling of the older breeding flock. The short- and long-run cross-elasticities of supply with respect to lamb prices implied by equation (1) are +.185 and +.351, respectively. In contrast to our results, Powell and Gruen [18, p. 78] obtained an estimated one year cross-elasticity of −.0177.

Finally, the fertilizer variable enters with the expected positive sign in both equations and seems to be a good proxy variable for technological changes in Australian production. These coefficients indicate that a *certeris paribus* increase in the use of superphosphate fertilizer of one thousand metric tons implies an increase in wool production in the following year of 381 to 583 thousand pounds (clean basis).

New Zealand Wood Production

The New Zealand sheep industry, second largest producer of apparel wool in the world, has a number of characteristics that differentiate it from that of Australia. Most of the New Zealand wool clip is of a coarser crossbred variety, grown on sheep more suited for the production of lamb than are the Merino sheep of Australia. In many areas, lamb production is the important crop and wool is just a by-product. However, there are no significant substitute farm crops. Variations in weather seem to have less effect on wool production in New Zealand than in Australia, and inclusion of a rainfall index in its equations yielded negative results. Finally, a Reserve Price Scheme, in operation since 1952, sets a guaranteed floor price for wool and thus protects producers from the more extreme drops in world wool prices. Because of this floor under wool prices, and because of the relative unimportance of droughts, annual wool production could be expected to vary considerably less in New Zealand than in Australia; and indeed, this was true over the time period studied.

The variables used in the two New Zealand wool production equations, given below, are current and lagged seasonal production in millions of pounds (clean basis), Wnz_t and Wnz_{t-1}; the deflated world wool price in U.S. cents per pound in season $t-2$, Pw_{t-2}; the deflated New Zealand reserve price for wool in U. S. cents per pound in season $t-1$, $Rpnz_{t-1}$ (this price is announced at the end of season $t-2$); and the deflated price of New Zealand lamb in U. S. cents per kilogram in the first calendar year of season $t-2$, $Plnz_{t-2}$.[8] Each equation was estimated by the Cochrane-

---

[8] For the years prior to the creation of the Reserve Price Scheme, $RPnz_{t-1}$ was set equal to the deflated world wool price. The lamb price series used is the opening schedule price for top grade lamb determined by the New Zealand Meat Producers' Board, published in [20].

Orcutt procedure, assuming the residuals follow second-order Markov schemes.

$$(3)\qquad Wnz_t = \underset{(.021)}{1.003Wnz_{t-1}} - \underset{(.086)}{0.086Pw_{t-2}} + \underset{(.260)}{0.406Plnz_{t-2}}$$

$$R^2 = 0.99, \quad s.e. = 5.852, \quad D.W. = 1.71, \quad B = -0.003,$$
$$p_1 = -.650, \quad p_2 = -.284$$

$$(4)\qquad Wnz_t = \underset{(0.020)}{0.961Wnz_{t-1}} + \underset{(0.057)}{0.155RPnz_{t-1}} + \underset{(0.090)}{0.296Plnz_{t-2}}$$

$$R^2 = 0.99, \quad s.e. = 3.610, \quad D.W. = 1.86, \quad B = 0.039,$$
$$p_1 = -.959, \quad p_2 = -.542$$

The two different forms of the New Zealand equations were estimated in order to find out whether the reserve price or the actual wool price is most relevant to production decisions. In both cases, the Cochrane-Orcutt procedure seemed to work quite well, for the Durbin-Watson statistics for the ordinary least squares estimates of (3) and (4) were 2.9 and 3.2, respectively. Equation (3) is not very promising, for wool prices enter with the "wrong" sign and with little explanatory power, and the estimated coefficient of adjustment is negative. Equation (4) indicates that the reserve price variable has considerably more explanatory power with respect to wool production, probably because New Zealand wool producers are more concerned about a floor to their expected future earnings from wool sales than about attempting to forecast the fluctuations in world wool prices. Such behavior would be most probable for producers who consider lamb their main crop. If this inference is correct, one of the main objectives of the Reserve Price Scheme is being achieved—that of protecting wool producers from some of the extreme variations of the market and thereby stabilizing and encouraging production. The estimated short-run (two year) and long-run (equilibrium) elasticities of wool production to the reserve price obtained from (4) are 0.028 and 0.718, respectively. Because of the very small estimated value of the adjustment coefficient, the equilibrium elasticity is that corresponding to quite a long period of adjustment. While wool production appears to be stabilized by the Reserve-Price Scheme, the inelasticity of wool production with respect to the reserve price implies that it would be difficult for the New Zealand Wool Commission to use this policy variable to obtain a significant short-run increase in wool production. However, since the New Zealand reserve price was set quite conservatively throughout the observation period, it is difficult to estimate the effects of a more aggressive policy; for such a policy change might cause the price coefficient to change. The estimated short- and long-run cross-elasticities of production to lamb prices from (4) are 0.044 and 1.333, respectively. These results indicate that New Zealand wool production is more sensitive to lamb prices in the long run than that of Australia, as was expected, but the short-run effect is surprisingly low.

McMahnon [12, p. 38] states that the impact of technological change in New Zealand wool production has been quite impressive, with the stock-carrying capacity of some pastures being doubled in the last twenty years. However, we were not able to isolate any proxy variable for this technological change. When a fertilizer variable similar to that used in the Australian equations was included in (4), it entered with a negative sign and had no explanatory power.[9]

South African Wool Production

The wool industry of the Union of South Africa is in many ways similar to that of Australia. The climate in most sheep farming areas is very dry, with seasonal wool production affected by droughts in many years. Because of this climate, most of the sheep raised are Merino, grown only for wool production; hence, no lamb price variable was included in the South African equations. Wheat is a substitute crop for sheep farming only in some areas that are not too dry. South African wool production has not grown at the rate of Australian or New Zealand production, principally because of the prevalence of infectious and erosion diseases of sheep, the effects of vermin, and periodic droughts. Diseases and vermin have been difficult to control, but some progress has been made. In this area, as well as in improving water resources and fencing pastures, technological improvements have taken place; but because data are lacking, this factor was not included in the regressions. In March, 1958, South Africa began a Reserve Price Scheme similar to that of New Zealand, but the South African Wool Commission is at a disadvantage, compared with that of New Zealand, for it has less capital. Furthermore, South Africa does not have as strong a position in the world market in types of wool it produces. It is probably for these reasons that, unlike the New Zealand Wool Commission, the South African Wool Commission did not vary the reserve price during the period studied. However, the "real" value of this price has changed, because of changes in the deflator price index.

The data used in the two South African equations given below are current and lagged seasonal wool production in millions of pounds (clean basis), Wsa_t and Wsa_{t-1}; the deflated world wool price in U. S. cents per pound in season $t-2$, Pw_{t-2}; the deflated South African reserve price for wool in

---

[9] The value of the coefficient of lagged production is probably unreasonably high in equation (4); and if so, this upward bias may be due to this lagged term picking up some of the effects of technological improvements in New Zealand sheep farming.

U. S. cents per pound in season $t-1$, $RPsa_{t-1}$ (this price is announced at the end of season $t-2$); the deflated price of wheat in U. S. cents per pound for the first calendar year of season $t-2$, $Pwhsa_{t-2}$;[10] and a South African rainfall index for season $t-1$, Rsa_{t-1}. The one year lag in this rainfall series was necessitated by the time period of the available series, and, therefore, the effect of droughts may be underestimated.

As a test of the effect of the Reserve Price Scheme, two equations were estimated, equation (5) containing just the world wool price variable and equation (6) containing also the reserve price variable. Because the observation period for which the Reserve Price Scheme was in operation is small, no equation was estimated with the reserve price as the only wool price variable. In the years prior to the formation of the Reserve Price Scheme, the variable $RPsa_{t-1}$, was set equal to zero. Thus, this variable probably should be interpreted as a "shift variable" in (6), indicating how wool production in the last six years compared with that of earlier years. Both equations were estimated by ordinary least squares.

$$(5)\quad \underset{}{Wsa_t} = \underset{(0.047)}{0.900Wsa_{t-1}} + \underset{(0.062)}{0.108Pw_{t-2}} - \underset{(0.068)}{0.079Pwhsa_{t-2}} + \underset{(0.074)}{0.141Rsa_{t-1}}$$

$$R^2 = 0.92, \quad s.e. = 7.840, \quad D.W. = 2.20, \quad B = 0.100$$

$$(6)\quad Wsa_t = \underset{(0.065)}{0.868Wsa_{t-1}} + \underset{(0.072)}{0.133Pw_{t-2}} + \underset{(0.060)}{0.044RPsa_{t-1}} - \underset{(0.070)}{0.085Pwhsa_{t-2}}$$

$$+ \underset{(0.076)}{0.151Rsa_{t-1}}$$

$$R^2 = 0.92, \quad s.e. = 7.984, \quad D.W. = 2.08, \quad B = 0.132$$

Equation (5) appears to be quite good, with the signs of all coefficients coinciding with *a priori* assumptions and with an acceptable value of the Durbin-Watson statistic, 2.20. The low value of the coefficient of adjustment, 0.100, indicates that the adjustment of production in South Africa in response to changing economic factors is indeed a slow process.[11] The rainfall index variable enters with the expected sign, the coefficient of 0.141 indicating that a drop in the index of 1.00 in one season causes a drop in wool production in the next season of 141 thousand pounds (clean basis). Over the observation period, this index has varied between a low of 51 and a high of 135. The estimated short- and long-run elasticities of wool production to wool price are +0.076 and +0.764, respectively, values similar to those estimated for New Zealand. The estimated short- and long-run cross-elasticities of wool production to wheat prices are -0.050 and -0.497, respectively, the short-run elasticity being very close to that estimated for Australia.

---

[10] The wheat price used is the Government fixed price for wheat published in [20].

[11] Again, the lagged production variable may be picking up some of the effect of excluded technological improvement variables.

In equation (6), an estimate is made of the effect of the Reserve Price Scheme on South African wool production. The small positive coefficient of $RPsa_{t-1}$ suggests that the Reserve Price Scheme has had some effect in increasing wool production in the last six years of the sample period; but since the standard error of this coefficient is very large, this result is not conclusive. It is interesting to note that the supply elasticity with respect to Pw_{t-2} increases by some thirty percent when $RPsa_{t-1}$ is included. One would expect that the effect on this price elasticity would be asymetric, increasing the responsiveness of wool supply to price increases but decreasing the negative effects of price decreases.

Wool Production in Argentina and Uruguay

Argentina and Uruguay account for about 10 percent of the world's wool production, with Argentina producing wool of all qualities and Uruguay producing mainly crossbred wool. Wool production in Uruguay remained fairly constant over the sample period, while production in Argentina declined despite some attempts by the government to encourage production. A major factor in both countries has been unstable political climates accompanied by frequently changing export policies. In their attempts to fight inflation, balance of payments deficits, and other problems commonly faced by developing countries, the governments of these two countries sometimes have followed policies designed for revenue purposes and other times policies designed to stimulate exports. Another policy objective in Argentina has been to keep the cost of raw materials low for the growing domestic textile industry. The principal forms of government control in these countries have been export taxes, licenses and bonuses, and controlled exchange rates. The important effects of these changing policies on wool production greatly increase the difficulty of estimating supply equations for these two countries.

These difficulties are compounded by a lack of adequate data. In particular, no useable lamb price series was discovered for these countries. Also, while improvement of pastures contributed significantly to wool production in Uruguay during the sample period, no proxy variable for this pasture improvement was found. Finally, because of data limitations, the equations for these two countries were esitmated with data for 1950–1951 through 1964–1965, a sample period two seasons shorter than that used for the other countries in this study.

The major substitute products in Argentina are wheat and beef; in Uruguay, beef and hides (of cattle and sheep). Wool is Uruguay's most important product, accounting for as much as 60 percent of the country's export earnings in some years; and the importance of substitute crops is thought to be fairly small. In Argentina, the importance of substitute crops appears to be greater, except for regions in the far south. Rainfall in Uruguay is regular and adequate; and when a rainfall index was included in the Uruguay equations, the resulting coefficients were statistically highly insignificant. In contrast, the larger variations of seasonal rainfall in Argentina are thought to be a significant factor affecting wool production; and a seasonal rainfall variable is included in the final Argentine equation.

The resulting equations explaining wool production in Argentina and Uruguay are, respectively, equations (7) and (8) below. A one year lag is used in these equations instead of the two year lags used elsewhere in this study. When a two year lag was used, the results were even less satisfactory than these. The variables used in the Argentine equation (7), are Wag_t and Wag_{t-1}, Argentine wool production in millions of pounds (clean basis) in seasons t and $t-1$; Pw_{t-1}, the deflated world wool price in the United States cents per pound for season $t-1$; $Pwhag_{t-1}$, a deflated price of Argentine wheat in United States dollars per bushel for the first calendar year of season $t-1$; $Pbag_{t-1}$, a deflated price of Argentine beef in United States dollars per hundred pounds for the first calendar year of season $t-1$; and Rag_t, an Argentine rainfall index for season t.[12] The variables used for Uruguay in equation (8) are Wur_t and Wur_{t-1}, wool production in Uruguay in millions of pounds (clean basis) for seasons t and $t-1$; Pw_{t-1}, the deflated world wool price in United States cents per pound for season $t-1$; $Phur_{t-1}$, a deflated index of prices of Uruguayan hides for the second calendar year of season $t-1$; and $Pbur_{t-1}$, a deflated index of prices of Uruguayan beef for the second calendar year of season $t-1$.[13] Equation (7) was estimated by ordinary least squares; equation (8), by the Cochrane-Orcutt procedure, where the residuals were assumed to follow a second-order Markov scheme.

$$(7)\quad \underset{}{Wag_t} = \underset{(.178)}{.791\,Wag_{t-1}} + \underset{(.168)}{.010\,Pw_{t-1}} - \underset{(20.490)}{11.974\,Pwhag_{t-1}} + \underset{(1.883)}{1.769\,Pbag_{t-1}} + \underset{(.227)}{.305\,Rag_t}$$

$$\bar{R}^2 = .62, \quad s.e. = 16.718, \quad D.W. = 1.51, \quad B = .209$$

---

[12] The Argentine wheat price series used is the support price for years 1948 to 1950 and the unit value of exports for years 1951 to 1964, and the beef price is the unit value of exports of foreign beef. Both series are deflated by an export index which is an index of Latin American export prices for the years 1948–1950, and an index of Argentine agricultural export prices for the years 1951 to 1964. All of these series are published in [7].

[13] The hide index for Uruguay is an index of unit value export prices of cattle and sheep hides and the beef price index is an index of unit value export prices of frozen and canned beef. Both series are published in [7].

$$(8) \quad Wur_t = .561\,Wur_{t-1} + .251\,Pw_{t-1} + .103\,Pbur_{t-1} + .194\,Phur_{t-1}$$
$$\qquad (.123) \qquad\qquad (.109) \qquad\qquad (.093) \qquad\qquad (.087)$$

$$R^2 = .66, \quad s.e. = 3.439, \quad D.W. = 1.86, \quad B = .439,$$
$$p_1 = -\,.221, \quad p_2 = -\,.280$$

These equations are not very satisfactory. The standard errors of most coefficients are high; and while the F test for the Uruguayan equation ($F=7.77$) is significant at the one percent level, the value for the Argentine equation ($F=4.50$) is significant at the five percent level but not at the one percent level.

Argentine wool production appears to be quite inelastic with respect to wool prices, the estimated short- and long-run price elasticities being +.042 and +.202. The wheat price enters the Argentine equation with an expected negative coefficient, the short- and long-run cross-elasticities being −.078 and −.322. However, the beef price enters with an unexpected positive coefficient. The weak explanatory power of both of these variables is probably due partially to the fact that wheat and beef are not significant substitute crops in the important sheep raising region of Patagonia. The rainfall index does have an expected positive effect on wool production in Argentina, a decrease of 1.00 in the index implying a decrease in production of 305 thousand pounds (clean basis).

The wool price coefficient in the Uruguayan equation is of the right sign and is statistically significant. The estimated short- and long-run price elasticities of supply are +.212 and +.481, somewhat higher than those for Argentina; and, in fact, the short-run elasticity is the highest estimate obtained in this study. The coefficient of the beef variable is also unexpectedly positive in the Uruguayan equation, as is the coefficient of hide prices. While there may be some element of complementarity between the raising of sheep and cattle in these two countries, these unexpected positive signs are more likely the combined result of mis-specified equations and inadequate data.

United States Wool Production

In a number of ways, the United States sheep industry is quite different from the sheep industries considered thus far. United States has a fully developed, highly industrialized economy; the agricultural sector does not dominate the economy; and the sheep industry is not the most important component of this sector. Also, United States wool is not produced for export, for the United States is a net importer of wool, producing only about thirty percent of the amount consumed. Wool is grown and marketed in many different ways here; hence, in aggregating "fleece wools" (grown on small eastern farms), "territory wools" (grown on the western ranges), and "Texas wools," grown on fenced pastures, the resulting equation explaining aggregate United States wool production may not be as satisfactory as the results for other countries where this problem was less severe. A final distinguishing characteristic of the United States sheep industry is that, in the years 1955–1965, United States wool production was encouraged to some degree by the government, farmers being paid an "incentive price" greater than the market price for their wool. In spite of such incentives, wool production has stagnated, falling slightly from 122.5 million pounds (clean basis) in the 1948–1949 season to 119.1 pounds (clean basis) in the 1964–1965 season.

Because of government support schemes, U. S. wool producers have been partially protected from the world market, and a new wool price variable had to be developed for the United States equation. First it must be noted that, since United States wool production (shearing) takes place in the spring, data are collected on a calendar year basis. For 1955 to 1965, the wool price variable most relevant to wool production appeared to be the government incentive price for wool, administered under the National Wool Act of 1954, for this price was always greater than the average price received by United States farmers. Incentive or support prices of some sort also existed in 1948 to 1954, but these were always lower than the average price received. Thus, the wool price series used, $Pwus_t$, is the average price received by farmers in cents per pound for 1948 to 1954 and the National Wool Act incentive price for wool in cents per pound for 1955 to 0965.

For a large segment of the United States sheep industry, lamb seems to be the major product; wool, a secondary joint product; wheat and beef, the two most important substitute products. Although variations in rainfall certainly must affect wool production in the more arid wool raising areas of the United States, inclusion of a seasonal rainfall index for the whole country yielded negative results. This may be because this index does not adequately capture differences in weather among the different regions of the country. Finally, no way was found to isolate technological change in wool growing, but omission of this factor seems less important for the United States during 1948–1965 than for the other countries studied.

The estimate of the United States wool production equation (9) given below explains Wus_t, United States wool production in millions of pounds (clean basis) in year t, as a function of Wus_{t-1}; $Pwus_{t-2}$, the deflated United States effective wool price in cents per pound (clean basis) for year $t-2$; $Pwhus_{t-2}$, the deflated United States price of wheat in dollars per bushel for year $t-2$; and $Pbus_{t-2}$, the deflated United States price of beef in dollars per hundred pounds for year $t-2$.[14] All prices were deflated by the United States wholesale price index for farm products.

---

[14] The United States wheat price series used is the price of number 2 hard winter wheat in Kansas City published in [7]. The beef price series is the average price received by farmers published in [20].

Estimating the equation specified above for the years 1949 through 1965 with ordinary least squares yields

$$(9)\quad Wus = \underset{(47.521)}{96.901} + \underset{(.162)}{.548}\, Wus_{t-1} + \underset{(.151)}{.313}\, Pwus_{t-2} - \underset{(.154)}{.223}\, Pwhus_{t-2} - \underset{(.699)}{.641}\, Pbus_{t-2}$$

$$R^2 = .67, \quad s.e. = 5.39, \quad D.W. = 1.53, \quad B = .452$$

All of the variables enter (9) with the expected signs. Adding a lamb price variable, $Plus_{t-2}$, the deflated United States price of lamb in dollars per hundred pounds for year $t-2$,[15] to (9) yields

$$(10)\quad Wus_t = \underset{(77.348)}{83.592} + \underset{(.309)}{.606}\, Wus_{t-1} + \underset{(.180)}{.294}\, Pwus_{t-2} - \underset{(.154)}{.211}\, Pwhus_{t-2} - \underset{(.768)}{.695}\, Pbus_{t-2} + \underset{(1.327)}{.297}\, Plus_{t-2}$$

$$R^2 = .67, \quad s.e. = 5.39, \quad D.W. = 1.54, \quad B = .394$$

The coefficient of the lamb price variable has the expected (positive) sign but has a very large estimated standard error. The result is surprising, for lamb production is very important in many areas of the United States. Perhaps lamb production is not particularly responsive to lamb prices or the wrong lamb price variable was used. Since the estimates of the other coefficients of (10) seem less precise than those of (9), the following discussion concentrates on equation (9).

The estimated short- and long-run elasticities of wool production with respect to the United States wool price variable are +.145 and +.321. These are higher than most of the other estimates of price elasticities obtained in this study. The wool price coefficient indicates that a *certeris paribus* increase in the incentive price of wool of ten cents a pound would lead to an increase of about 3.1 million pounds (clean basis) in United States wool production in two years and a "long run" increase of about 6.9 million pounds. Yet this price was held at the same level in money terms since 1955, its "real" value varying only with changes in the wholesale index of farm products. These results suggest that a more vigorous use of the incentive price of wool would be an effective means of increasing United States wool production.

As for the other coefficients in (9), the estimated short- and long-run cross-elasticities of production, first, with respect to wheat prices, are −.387 and −.856; and second, with respect to beef prices, are −.100 and −.221. Thus, wheat appears to be a relatively strong substitute product and beef a weak substitute. The estimated coefficient of adjustment is .452, similar to the estimates for Australia and Uruguay.

---

[15] The lamb price series used is the average price received by farmers published in [20].

Conclusions

In general, the statistical properties of the equations explaining wool production in the six major producing countries appear to be reasonably satisfactory, although the standard errors of some coefficients are too high. The *F* tests are significant at the five percent level for all equations, and at the one percent level for all except the Argentine and United States equations. From the viewpoint of economic theory, the main deficiency in all the equations is the absence of cost variables. Another deficiency in all but the Australian equation is the lack of a variable for technological change. Considerable research is needed in order to integrate these two factors into the supply equations. It would be desirable also to disaggregate the countrywide equations into different regions and for different qualities of wool, whenever the data permit. Yet, despite these deficiencies, the equations developed in this study appear to give the approximate structure of the production side of the world wool market.

Since these equations are similar in several respects, it is possible to make some general observations about world wool production. Table 1 gives a summary of the estimates obtained for the coefficients of adjustment, as well as the wool, lamb, and wheat price elasticities of supply. First, by using

Table 1. Summary of estimates of coefficients of adjustment and price elasticities of supply

		Coefficient of adjustment	Wool price elasticity		Lamb price cross-elasticity		Wheat price cross-elasticity	
			Short run	Long run	Short run	Long run	Short run	Long run
Australia	(1)	.527	.066	.125	.185	.351	−.046	−.087
	(2)	.305	.084	.276	—	—	−.046	−.150
New Zealand	(4)	.039	.028[a]	.718[a]	.044	1.133	—	—
South Africa	(5)	.100	.076	.764	—	—	−.050	−.497
Argentina	(7)	.209	.042	.202	—	—	−.078	−.372
Uruguay	(8)	.439	.212	.481	—	—	—	—
United States	(9)	.452	.145[b]	.321[b]	—	—	−.387	−.856
	(10)	.394	.136[b]	.346[b]	.048	.121	−.367	−.932

[a] These estimates are of the elasticity of New Zealand wool production to the New Zealand Reserve Price for wool.

[b] These estimates are the elasticity of United States wool production to the effective United States wool price as defined in the text.

a model incorporating an adjustment lag, this study shows that wool production is indeed quite stable in all of these countries, varying only slightly and after a long lag in response to changing economic factors. The estimated coefficients of adjustment range from an extremely low .04 for New Zealand to a high of .53 for Australia. The estimates of the elasticity of wool production to wool prices vary from +0.02 to +0.21 for the short run and from +0.12 to +0.72 for the long run. The inelasticity of wool supply to wool prices in all but the very long run is, therefore, an important aspect of the world wool market. The effects of substitute products (wheat, cattle) and of the joint product, lamb, on wool production also are estimated to be quite small. Thus, we would not expect to find in wool production the strong cycles that have been observed in the production of other agricultural products for which the supply responses to changing economic factors are considerably stronger, such as hogs in the United States. Instead, we would expect weaker cycles of fairly long duration; and such cycles have been detected by spectral analysis of wool production in Australia [22, Chapter 8]. There is considerable evidence, also, that the consumption of wool is quite inelastic with respect to wool prices [22, Chapter 6]. These results suggest that when supply or demand shifts due to some exogenous shock, such as a drought, or a recession in the consuming country, or a war, the resulting variations in wool prices and stocks will be much greater than they would be if these supply and demand relationships were more price elastic. Indeed, this has been the case in the post-war period during which world wool prices and stocks fluctuated very widely.

Estimation of Performance Functions for Budgeting and Simulation Studies*

WILFRED CANDLER AND WAYNE CARTWRIGHT

This paper discusses the use of ideas from experimental design, and regression analysis, to increase the generality of result obtained from budgeting and simulation studies.

THIS paper discusses the problem of estimating the *functional relationship* between the variables used in budgeting and simulation studies and the use of these functions in deriving "performance statistics."

In particular, this paper considers the situation where a research worker has completed a major budgeting (or simulation) study and is thus in a position to state what outcomes would result under the assumptions made when specific values are assigned to the variables. These specific values of the variables might refer, for instance, to product prices (or price elasticities of demand), crop yields, labor requirements, weather variables, rate of interest, or the size of production quotas. The outcome of interest might refer, for example, to the present value of a project, maximum indebtedness, income variability, or rate of increase in production. In short, the completed study allows the impact of specific assumptions about the variables to be converted into estimates of the resulting outcomes.

The problem considered in this paper involves the derivation of more general functional relationships between the variables used in the study and the resulting outcomes. Once these functional relationships have been derived, the outcomes associated with given levels of the variables can be estimated directly from the functional relationship without having to go through the possibly tedious and costly process of inserting values for the variables in the budget or simulation.

If the research worker is considering a problem with a clearly defined objective function, and is interested only in the levels of decision (that is, controllable) variables, then it is reasonable for him to attempt to find the *optimum* level of these variables. Where the research worker is interested in optimization, he can use the approach suggested by Zusman and Amiad [8] or the ideas discussed in the engineering literature on control theory.

There are many instances, however, where the research worker is *not* faced with an optimization problem but has an estimation problem. The estimation problem can arise from either, or both, of the following considerations:

---

* A first draft of this paper was written while the authors were at Massey University, New Zealand. The authors would like to acknowledge the helpful comments of L. Eisgruber.

WILFRED CANDLER *is professor of agricultural economics and* WAYNE CARTWRIGHT *is research assistant in agricultural economics, Purdue University, Lafayette, Indiana.*

(1) The components of the decision maker's objective function (such as debt and risk aversion) may be known, but their relative weights are unknown; or

(2) Some of the important variables used in the study (such as price) may be exogenous, and not under the control of the decision maker.

In these cases, the problem does not involve optimization; rather, it involves the estimation of the values of the components of the objective function that would be associated with particular levels of the decision and exogenous variables.

The ideas discussed in this paper are illustrated with reference to a budgetary study of the profitability of sheep farm development.[1] This study involved interacting occurrences of borrowing, taxation and debt repayment over a period of more than ten years. This meant that the construction of individual budgets to estimate present value and maximum indebtedness was extremely laborious and, in fact, involved the use of a specially written computer program. By using a central composite design[2] and completing the development budget for the 25 combinations of levels of four independent variables indicated by this design, it was possible to derive explicit functions of present value of farm development and maximum indebtedness in terms of the four major variables: wool price, stock prices, personal drawings and the price of fertilizer.

As shown in the conclusions to this paper, these performance functions allowed much more general conclusions to be drawn about the profitability of sheep farm development than would have been available from simple budgetary results.

Model Variables and Performance Statistics

Before proceeding, it is necessary to digress briefly to define some important components of budgeting and simulation models. *Structural parameters* are not subject to control by decision makers, but still determine the behavior of models. *Decision variables* also influence models' behaviour, but *are* subject to control by decision makers. The distinction depends largely on the level at which the decision maker operates.

In operation, a budgeting or simulation model generates *performance statistics*, which express the performance of the model. In this paper, we are concerned to express performance statistics as explicit functions, termed *performance functions*, of the structural parameters and decision variables.

If a model generates only one relevant performance statistic, or if the relative weights to be attached to multiple performance statistics are made explicit by the decision maker, we can talk of estimating an objective function. However, when we lack the relevant weighting information, it is reasonable to estimate the performance function for each of the performance statistics that may enter the ultimate objective function.

---

[1] Cartwright [3, pp. 218–272].

[2] We shall discuss the rationale of using this design later in this paper.

Budgeting and Simulation

Deterministic budgeting studies generally involve point estimates of structural relationships and unique values of the decision variables. Each decision alternative being budgeted then provides single-valued estimates of the performance statistics. Simulation studies, on the other hand, usually involve well defined structural relationships and the variation of at least one decision variable.

Nevertheless, as mentioned above, budgetary studies become more flexible when variables are explicitly introduced.[3] At this point the methodologies of budgeting and simulation become almost indistinguishable, but it is notable that the performance statistics in budgeting studies are generally stated as explicit functions of the variables of the model.[4] Thus one suitable distinction between budgeting and simulation might be, "budgeting is a form of simulation in which the performance statistics are expressed as explicit functions of the variables in the model."[5]

For the balance of this paper, no distinction is made between budgeting and simulation studies.

Experimental Approach

If we represent the n performance statistics for a simulation model as S_i; $i=1, \cdots, n$ and the m variables of the model as x_j; $j=1, \cdots, m$, then there is some functional relationship between the statistics and variables:

$$S_i = f_i(x_1, \cdots, x_m); \qquad i = 1, \cdots, n. \tag{1}$$

---

[3] The introduction of variables to represent prices and technical coefficients in budgeting is, of course, not new. This procedure has been called parametric budgeting [2, 7].

[4] See, for instance, Lloyd's [7, p. 8] budgetary equation for the net revenue per ton of hay conserved, as a function of the model parameters:

$$N = \frac{E}{5.5P}(10.6W - 185) - (H + 288)$$

where

N = Net revenue per ton of hay conserved (in pence),
W = Wool price net of marketing costs (in pence),
E = Technical efficiency of hay-making (in food units per ton),
P = Average period of feeding (in weeks per annum), and
H = Cost per ton of hay (in pence).

[5] This would mean, however, that in some "budgetary" studies involving for instance, farm development, decisions made over several years would need to be classified as "simulations." These long term development budgets frequently involve interactions between level of indebtedness, tax payments, and interest payments which are non-linearly related and extremely difficult, if not impossible, to represent as explicit functions.

The functions, f_i, may be extremely complex, but they can often be approximated by standard functional forms such as the polynomial. (In general, for curvilinear functions, the higher the order of the polynomial the better the degree of approximation.) Of course, prior knowledge could lead to the selection of functional forms other than polynomials. If there are *a priori* reasons for believing that the functions are of markedly different form in different regions of the performance space, a separate function could be used in each region to approximate (1).

For a discussion of the problems of:

1. Selecting an appropriate functional form for (1); and
2. Deciding on the optimum degree of replication if (1) is stochastic,

the reader is referred to the literature on experimental design as reviewed in Heady and Dillon [5]. This paper considers the use of a second order polynomial, though obviously other forms could have been used if *a priori* information had indicated that they were likely to give a better representation of the structure of the model.

To approximate the performance function (1), for the case where $n=1$ and $m=3$, by a second order polynomial, we would need to estimate the ten parameters of the following function:

$$(2) \qquad S = b_0 + b_1x_1 + b_2x_2 + b_3x_3 + b_{11}x_1^2 + b_{22}x_2^2 + b_{33}x_3^2 + b_{12}x_1x_2 + b_{13}x_1x_3 + b_{23}x_2x_3.$$

To fit this equation, a minimum of ten runs of the simulation would be required with appropriate combinations of values of x_1, x_2, and x_3.

In practice, we would want to make more than ten runs of the simulation, since the extra observations would provide us with some measure of the likely error in using (2) to infer the value of S for non-simulated values of x_1, x_2, and x_3.

If the simulation model is non-stochastic, there will be only one outcome, S, for each set of x_1, x_2, and x_3, and hence re-running the simulation several times for the same set of parameters will not add any new information.

If a stochastic simulation is being used, however, replication (or re-running) of the simulation for given sets of parameters will increase the reliability of our estimates of the expected value of the performance statistic and provide information on the variance of outcomes at this particular point.

The form of the performance function (1) to be used and the selection of the number and location of parameter sets to be used for simulation runs both involve the same arguments about experimental design which arise in connection with the derivation of production functions [5]. The possibility of using gradient methods to locate the optimum operating conditions in a simulation study has already been noted by Zusman and Amiad [8]. However, whereas their objective was to locate a specific region or point on a performance surface, we are more concerned with estimating the performance surface *throughout* the space corresponding to selected ranges of the variables $x_1, \cdots, x_n$.

Numerical Example

The authors formulated the idea of deriving a performance function in connection with a substantial budgetary study of the potential for increased production on sheep farms in Wairoa County, New Zealand [3]. This study involved a fixed technical pattern of farm development over a nine year period and the examination of the financial implications of this development under a number of price and income assumptions.

Budgeting the implications of even one parameter set was quite complicated because of the interaction of taxation, interest paid, and overall level of indebtedness. In one case pay-back was predicted to occur in the 37th year!

The performance statistics of interest were:

S_1 = Present value of extra pre-tax cash profits,
S_2 = Present value of extra post-tax cash profits, and
S_3 = Maximum overdraft.[6]

The first of these performance statistics measures, in a sense, the worth of the development program to the nation. The second measures its worth to the individual undertaking the development, and the third statistic provides a measure of the financial feasibility of the development program.

The model variables of interest were:

x_1 = Price index for sheep and cattle,[7]
x_2 = Price of wool (net, greasy basis),
x_3 = Price of fertilizer (including application charges), and
x_4 = Lower bound on owner's annual personal drawings from the farm.

A second order polynomial equation was fitted for each performance statistic as a function of the four parameters, using a central composite design [1, 5] to define the levels of the variables to be used.[8] At each "treatment combination" (i.e., for each set of variables), the development program was budgeted (on the computer), and hence the values of the three performance statistics were obtained.

---

[6] Expressed more descriptively, these performance statistics represent:
S_1 = Present value of the development program, if we ignore taxation (or assume a zero tax rate),
S_2 = Present value of the development program, if we treat taxation as a cost (just like fertilizer),
S_3 = The maximum indebtedness which has to be incurred to finance the program.

[7] The base index (=100) represented the prices that the authors believed most likely to rule in the future. Changes in the index should be interpreted as proportional changes in the prices of all sheep and cattle. The specification of separate indices (parameters) for different classes of sheep and cattle was not thought to be justified in the present study.

[8] When, as in our budgeting study, the cost of obtaining 'observations' of performance statistics is high, it is important to use a design which is efficient in yielding small magnitudes of residual sums of squares when the function to be fitted is given and the number of observations is fixed. The central composite design appears to be particularly suitable in this respect, although we do not claim that it is necessarily the most efficient design available.

To fit a second order polynomial in four variables, fifteen coefficients have to be estimated. The appropriate central composite design involves twenty-five "treatment combinations," so that for each equation ten degrees of freedom remained after estimating the fifteen coefficients.

The least-squares estimates of the coefficients for the polynomials, and the coefficient of multiple determination, R^2, appear in Table 1. We should be careful in interpreting these estimates. Note that the observations were known with *certainty*, so that the regression model was actually non-stochastic and did not conform to all the assumptions of the General Linear Model. Nevertheless, in these circumstances, it is permissible to use a least-squares procedure provided that R^2 is regarded as a measure of the adequacy of the polynomial in approximating the shape of the actual function. In a non-stochastic model, the standard errors obtained from least-squares regression have no meaning.

Table 1. Model development program—budgetary performance functions

Regression coefficient	Present value of pre-tax development cash profits	Present value of post-tax development cash profits	Maximum overdraft
b_0	154,280.29000	76,243.16700	−35,702.35000
b_1	292.84060	327.23935	−227.36661
b_2	3,107.10900	883.97287	−880.03005
b_3	−20,178.39000	−10,567.80200	8,124.19000
b_4	−118.73740	−45.77737	42.06840
b_{11}	4.77284	.43631	−.36150
b_{22}	−.61516	−.26265	.18215
b_{33}	568.58099	226.17605	−178.57379
b_{44}	.02448	.00951	−.00799

b_{34}	.37018	−.32665	0.01724
R^2	.967	.994	.997

It will be noted that the coefficient of multiple determination, R^2, for the estimation of present value of extra pre-tax cash profit, S_1, is only .967 versus .994 for S_2 and .997 for S_3. While the relatively low R^2 for S_1 may warrant a more careful comparison of actual and estimated values of this statistic,[9] the authors would feel fairly safe in using all three functions to approximate the results which would be obtained by budgeting.

---

[9] Even if the function estimating S_1 had proven unacceptable, this result would not have

Interpretation of the Performance Function

An initial, slightly ironic, observation is that the derivation of acceptable performance functions presents the analyst with an almost embarrassing amount of information.

More specifically, the performance functions allow estimation of:

1. Performance statistics (in this case, budgeting outcomes) for any reasonable values of the variables $x_1, \cdots, x_n$;
2. Estimation of the slope of the functions at any point; this allows measurement of the sensitivity of the performance statistics to marginal changes in the variables of the model; and
3. Location of break-even points; that is, combinations of the variables that result in performance statistics of zero.

The following examples illustrate the computations suggested above. The examples discussed are not, of course, exhaustive.

Point Response: Consider the question, "What would be the estimated present value of extra post-tax cash profits and maximum overdraft from the example farm development program if future prices are assumed to include stock prices at 120% of base prices, wool prices at 38.5d net, fertilizer costing £14/12/– per ton applied, and the lowest annual personal drawings that the farmer will tolerate are £1,050?"

Appropriate substitution in the response functions given in Table 1, gives estimated performance statistics of:[10]

Present value of post-tax development cash profits

$$S_2 = \text{£}112{,}729$$

---

detracted from the usefulness of the technique. A third-order polynomial could have been fitted in an effort to obtain better predictions and still higher-order polynomials could subsequently have been tried. To fit a third-order polynomial, it would have been necessary to compute approximately 25 further evaluations. This did not seem justified. Alternatively, the second-order polynomial could have been fitted with the independent variables altered over smaller ranges. This could have increased the accuracy of fit.

[10] i.e., $x_1 = 120$, $x_2 = 38.5$, $x_3 = 15.6$ and $x_4 = 1{,}050$. Substituting in the appropriate function from Table 1, we have:

1. *Present value of extra post-tax cash profits*

$$\begin{aligned} S_2 = {} & 76{,}243.16700 + (120)(327.23935) + (38.5)(883.97287) \\ & - (14.6)(10{,}567.80200) - (1{,}050)(45.77737) + (120)^2(.43631) \\ & - (33.5)^2(.26265) + (14.6)^2(226.17605) + (.00951) \\ & - (120)(38.5)(11.65964) + (120)(14.6)(6.08840) + (120)(1{,}050)(.06299) \\ & + (33.5)(14.6)(45.16394) + (38.5)(1{,}050)(.39259) - (14.6)(1{,}050)(.32665) \end{aligned}$$

$S_2 = 12{,}729$, and

2. *Maximum overdraft*

$$\begin{aligned} S_3 = {} & -35{,}702.35000 - (120)(227.36661) - (38.5)(880.03005) \\ & + (14.6)(8.124.19000) + (1{,}050)(42.06840) - (120)^2(.36150) \\ & + (38.5)^2(.18215) - (14.6)^2(178.57379) - (1{,}050)^2(.00800) \\ & + (120)(38.5)(7.32207) - (120)(14.6)(4.36824) - (120)(1{,}050)(.04526) \\ & - (38.5)(14.6)(17.38524) - (38.5)(1{,}050)(.19627) - (14.6)(1{,}050)(.01724) \end{aligned}$$

$S_3 = 16{,}668$

Maximum overdraft

$$S_3 = £116{,}668$$

Thus, the derived functions may be used directly to estimate budgetary outcomes. It is important to note that extrapolation of the performance functions outside the ranges of values used to obtain them is unlikely to give reliable estimates of the performance statistics. Point responses could, of course, be obtained by direct budgeting, but our procedure promises to be less costly when individual budgets are complex and several point responses must be evaluated.

Graphical representation: If two of the parameters are set at constant levels, it is a simple matter to graph the performance statistics in terms of the other two parameters. Three of the possible graphs which could be drawn are shown in Figure 1, illustrating the ease with which the performance function can be interpreted. The curved lines are *iso-performance curves;* that is, the budgetary outcome is estimated to be constant with respect to a particular dimension (S_2 in these graphs) along any particular curve.

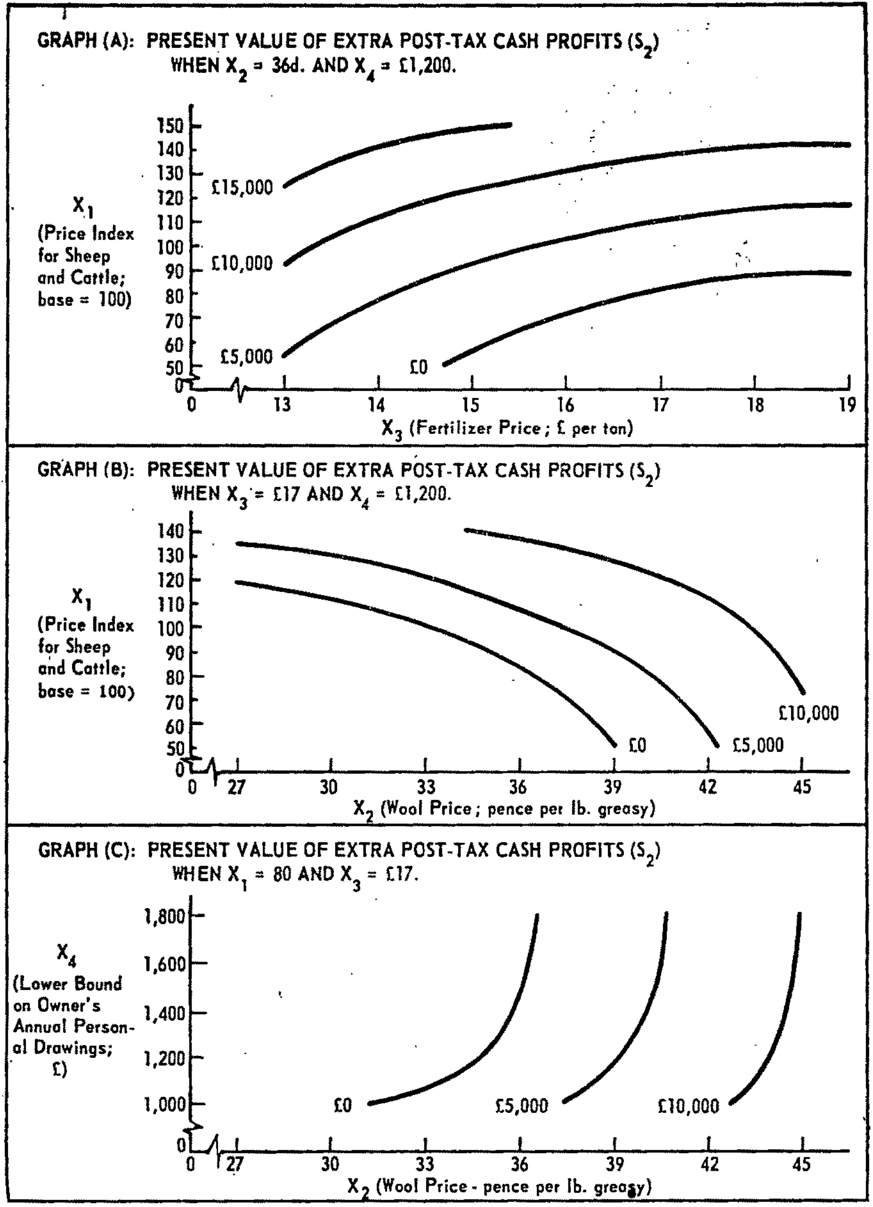
Graphs (A), (B), and (C) in Figure 1 show the effect on the estimated present value of extra-tax cash profits of varying x_1 and x_3, x_1 and x_2, and x_4 and x_2, respectively. The constant levels of the other variables are clearly indicated in each graph.

Sensitivity of performance function: The slope of the performance surface at any point denotes the sensitivity of the dependent variable to marginal changes in the independent variables. The slope of the performance surface with respect to a particular variable is obtained by taking the appropriate partial derivative of the function.

'Break-even' points: Suppose that we wish to obtain the values of the model variables for which the present value of extra post-tax cash profits, S_2, is zero. If three of the independent variables are set at particular levels, it is obvious that the S_2 performance function becomes a simple quadratic function in the remaining variable. For example, if the levels of x_2, x_3, and x_4 are regarded as constants, the response function may be written (in the notation of equation (1)) as:

$$(3)\quad S_2 = b_{11}x_1^2 + (b_1 + b_{12}x_2 + b_{13}x_3 + b_{14}x_4)x_1 + (b_0 + b_2x_2 + b_3x_3 + b_4x_4 + b_{22}x_2^2 + b_{33}x_3^2 + b_{44}x_4^2 + b_{23}x_2x_3 + b_{24}x_2x_4 + b_{34}x_3x_4).$$

This simple quadratic equation may then be solved for $S_2 = 0$. If real roots exist, and if at least one of these roots is within the specified range of x_1, then the 'break-even' level of x_1 (at the assumed combinations of levels of x_2, x_3, and x_4) will be obtained. Otherwise, no 'break-even' level exists within the range of the function.



GRAPH (A): PRESENT VALUE OF EXTRA POST-TAX CASH PROFITS (S_2) WHEN X_2 = 36d. AND X_4 = £1,200.

GRAPH (B): PRESENT VALUE OF EXTRA POST-TAX CASH PROFITS (S_2) WHEN X_3 = £17 AND X_4 = £1,200.

GRAPH (C): PRESENT VALUE OF EXTRA POST-TAX CASH PROFITS (S_2) WHEN X_1 = 80 AND X_3 = £17.

Figure 1. Iso-performance curves

Conclusions

Although the performance functions derived have not been examined in great depth in this paper,[11] the merit of the technique has been illustrated.

---

[11] A more detailed numerical analysis of the estimated performance functions appears in [3]

The chief advantages that this technique adds to conventional budgeting or simulation are:

1. Given an acceptable derived function, performance statistics for an infinite number of combinations of prices may be estimated *without* recourse to additional budgeting or simulation. These estimates may be useful *per se*, or they may serve to suggest the price combinations for which further budgets and simulations should be carried out. It is a simple matter to construct graphs from which performance statistics can be 'read off'.
2. The sensitivity of performance statistics to price changes can be directly estimated from the derived function. This facility is simply not available from budgeting or simulation without the (at least implicit) calculation of performance functions.
3. Combinations of model variables which yield particular outcomes (e.g. zero profits) can be computed readily. Conventional budgeting and simulation can provide this information, but only through explicit search procedures.

The chief limitation of this technique is that the number of runs of the simulation required to estimate the response function increases rather rapidly as we increase the number of independent variables and/or the degree of the polynomial function being fitted. It would, for instance, be quite expensive to fit a second order polynomial with more than 8 independent variables.[12]

Finally, we may quote one paragraph of the conclusions from the study [3, p. 271] in which the above performance functions were derived:

"It was apparent that the development should remain profitable to the Nation over virtually all foreseeable price combinations. The analysis suggested that development should be profitable to farmers over most price combinations, although for wool prices lower than 33d and sheep and cattle prices lower than 75% of base prices, development could be unprofitable, particularly at fertilizer prices higher than £15 per ton."

Obviously, it would have been extremely difficult to be confident of this conclusion without the information provided by appropriate performance functions.

[12] For appropriate search procedures for finding the optimum with more than 8 independent variables, see the work of Cyert and March [4, Chapter 8] and Hoggat and Balderson [6]. Where the research worker wants to estimate the performance function with more than 8 variables, the best approach is likely to be a more modest objective. The performance function with up to 8 independent variables can be estimated with other variables held constant (*ceterus paribus*). A variety of combinations may, of course, be chosen, so that several hyper-sections through the total performance function can be obtained.

Reliability of Supply Equations Derived from Production Functions*

LARRY J. WIPF AND D. LEE BAWDEN

This paper examines the reliability of supply functions derived from empirically estimated production functions. Firm-level supply equations are derived from production functions for selected agricultural commodities, and these are used to predict firm output and to estimate supply elasticities. The results are then compared with actual or expected output and with supply elasticities estimated directly by regression analysis of time series data. Output predictions ranged from slight under-estimates to extreme over-estimates of actual output, with the latter being most prevalent. The derived supply elasticities were generally higher than those obtained by direct regression analysis.

MICROECONOMIC theory tells us that if factor prices are known and profit maximizing behavior is assumed, a firm's supply curve can be derived from its production function. Further, these individual curves can be summed to obtain the industry supply curve, assuming negligible or offsetting external economies and diseconomies of scale. Armed with such a simple and universally taught principle, it is perhaps paradoxical that empirical estimation of supply has rarely followed this approach, even in industries in which perfect competition is approximated. Most supply equations have been estimated directly by regression analysis of time series data, presumably in the belief that the derived supply approach is less accurate for both descriptive and predictive purposes. In a survey article on agricultural supply analysis, Nerlove and Bachman concluded that "too few studies have been conducted in which supply functions have been derived from production functions . . ." [3, p. 533], and suggested that this is one area which warranted some further research.

This paper reports an attempt to evaluate the descriptive and predictive reliability of the derived supply approach. Supply equations for individual firms are derived from production functions for a few selected agricultural commodities, and these are used to predict firm output and to estimate supply elasticities. These results are then compared with actual or expected output and with supply elasticities estimated directly by regression analysis of time series data. All production functions and direct regression supply elasticities are taken from secondary sources.

---

Theoretical Considerations

The mechanics of deriving a supply function from a production function are presented in numerous textbooks and will not be repeated here. However, it might be helpful to consider briefly the limitations embodied in this approach. Implicit in this derivation is that firms not only desire to maximize profits, but in fact are able to do so; i.e., all variable resources are available in unlimited quantity and are used at their economic optimum, firms possess perfect knowledge of present conditions, and future prices are known with certainty. The procedure usually ignores the effect on output of substitute and complementary production alternatives not now being produced. Finally, it is assumed that the basic production relationships can be accurately estimated.

On the positive side, the method of deriving supply equations from production functions can explicitly recognize varying degrees of asset fixity; hence, alternative supply functions corresponding to different lengths of run can be estimated. Also, some allowance can be made for technological change by using production functions estimated at different points in time.

The more common method of estimating supply relations, by regression analysis of time series data, attempts to measure how producers have reacted in the past to changes in relevant variables, rather than how they *should have* reacted according to the profit maximizing criterion. This approach can incorporate the effects of substitute and complementary production alternatives. Obviously, predictions are based upon the assumption that producers will continue to act in the future as they have in the past.

Empirical Comparisons

A large number of commodity and "whole-farm" production functions have been estimated for various agricultural sectors.[1] Some of these are utilized in this study to evaluate the usefulness of the derived supply approach in predicting output and estimating supply elasticities.[2] Unless otherwise stated, the supply equations are based on logarithmic production functions fitted to individual farm, cross-sectional data.

Some supply equations were derived from production functions for crop- and livestock-type farms in various regions of the United States in 1950. These equations were then used to predict firm output and to estimate supply elasticities. The results are shown in Table 1, and compari-

---

[1] For a partial survey of these, see Heady and Dillion [1].

[2] Quite a few production functions fitted to agricultural data could not be used because prices or price indices for the input categories were not available or because they were incompletely reported.

Table 1. Output predictions and supply elasticities for various regions of the United States, 1950

Equation	Commodity	Area	Predicted output based on derived supply	Mean output of farm sample	Elasticity from derived supply	U.S. supply elasticity from direct regression
1	Crop	Montana	$ 60,630	$21,419	1.383	
2	Crop	N. Iowa	7,672	8,551	.197	.164–.172
3	Crop	S. Iowa	5,674	4,777	.647

sons are made of: (1) predicted (optimum) output per farm based upon the derived supply equation vs. the mean farm output of the sample, and (2) the corresponding supply elasticity vs. elasticity estimates from direct regression analysis. These estimates are for a short-run situation, in which land and labor in crop production and labor in livestock production are assumed fixed while capital services[3] are allowed to vary.

Predicted output per farm (optimum output consistent with profit maximization) from the derived supply equations corresponds fairly well with the mean output of the farm sample in five of the eight cases (equations 2, 3, 4, 6, and 8). Since capital is often limited in actual farm situations, one might expect predicted output to exceed the mean sample output, and this occurred in three of the five cases (equations 3, 4, and 6). Overestimation also resulted for equations 1, 5, and 7; but in at least the latter two cases, the degree of overestimation is extreme.

Unacceptable results may be due, in part, to the form of the underlying production functions.[4] The logarithmic function may yield unrealistic estimates of production coefficients (and hence of the derived supply function) at the extremes of the underlying data, since both increasing and decreasing marginal products cannot occur. In addition, the logarithmic production function imposes restrictions upon the *form* of the derived supply function, which may result in unrealistic predictions of output. In particular, if the sum of the exponents of the production function lies between one-half and one, the derived supply curve has a peculiar shape: given successive unit price changes, output increases at an increasing rate. This situation is more serious the closer the sum of the production elasticities is to one.[5] Thus, the logarithmic function might yield extremely large optimum outputs when the sum of the production elasticities approaches one. Such is the case with equations (5) and (7), the sum of the production elasticities (holding labor fixed) being .93 and .98, respectively.

---

[3] In these production functions, all capital items were aggregated into one input, although the individual items have varying degrees of fixity. This indicates the desirability of disaggregating inputs into finer categories than the traditional land, labor, and capital if the production functions are to serve as a useful basis for less than long-run supply prediction.

[4] A variety of functional forms have been used in empirical estimation of agricultural production functions. For a detailed exposition of alternative functional forms and the restrictions they place on the derived supply equations, see the discussion by Tweeten and Heady [5].

Direct comparisons of supply elasticities are not possible, but a general comparison can be made between the derived regional elasticities and elasticities estimated by regression analysis for the entire United States. For the crop equations, the derived elasticities ranged from about 15 percent to 800 percent larger than the directly estimated U.S. elasticity. The derived short-run elasticities for livestock appear intolerably high. Again, this may be attributed, in part, to the choice of the underlying production function. The logarithmic function has a constant supply elasticity; as such, it probably does not adequately represent elasticities at all product price levels.

Some additional short-run elasticity comparisons for specific commodities as well as for an entire farm are shown in Table 2. In the production functions upon which the derived elasticities are based, land, labor, farm improvements, and working assets are held fixed while liquid assets and cash operating expenses are free to vary. Again the derived elasticities exceed those estimated directly by the regression analysis, the former ranging from three to thirty times the latter.

A principal advantage of the derived supply approach is that it facilitates output predictions and elasticity estimates for various lengths of run. Consequently, supply equations were also derived from four whole-farm production functions, two for crops and two for livestock, with various combinations of inputs held fixed. The resulting elasticities and output predictions are shown in Table 3.

The results appear over-sensitive to changes in the length of run. For example, based upon the 1945 crop production function for southwestern Iowa (equation 1), farm production varies from $29,310, with land, labor, and machine services held fixed, to $9.4 billion per farm, with only land

---

[5] When the sum of the elasticities exceeds one, specific optimum output predictions are not possible because of increasing returns to scale. When such cases are encountered in the present analysis, one or more inputs are held fixed and short- or intermediate-run outputs and elasticities are derived.

held constant at 160 acres. The $9.4 billion output is due in part to a production function of nearly constant returns to scale; the sum of the production elasticities being .93. The corresponding supply elasticities range from .83 to 14.38, the latter over 17 times larger than the former. Similarly, the 1945 livestock estimates for southwestern Iowa (equation 3) seem to be over-sensitive to changes in the degree of asset fixity. On the other hand, somewhat reasonable changes in predicted output and supply elasticities are obtained from the 1954 crop and livestock production functions (equations 2 and 4).

Since the form of the basic production function is expected to have some influence on the accuracy of the derived supplies, an attempt was made to find different types of production functions for the same commodity. Estimated outputs and corresponding supply elasticities are shown in Table 4 for broilers, turkeys, hogs, and corn for each of the three basic forms of the production function—logarithmic, quadratic, and square root. The production functions are based upon experimental data. The derived supply equations are for the short-run, in which only the fertilizer input for corn and the feed input for livestock products are allowed to vary.

Estimated output and supply elasticities vary considerably by type of function. Elasticities are unrealistically high for all commodities using the logarithmic production function, and output predictions are clearly beyond existing technological capabilities. As before, this may be due in part to the sum of the production elasticities being somewhat larger than one half.

The quadratic yields a reasonable output prediction for broilers and somewhat realistic output and elasticity estimates for the first hog function and for corn. The negative supply elasticity for turkeys resulted from an unexpected sign of one of the production parameters.

Corn yields are realistic using the square root production function, and its derived elasticity compares favorably with that estimated directly by regression analysis. Here, too, one of the supply elasticities is negative (for the first hog function), indicating a problem with the sign of one or more coefficients of the production function.

Summary and Conclusions

Firm-level supply functions were derived from production functions for a variety of agricultural products and farm types. Supply elasticities and profit maximizing output were computed from these, and comparisons were made (1) with actual output and with elasticities estimated directly by regression analysis; (2) for different lengths of run using the same production function; and (3) among different types of production functions for a given commodity. The primary purpose was to ascertain

Table 4. Comparison of supply elasticities and estimated output from alternative types of production functions

Commodity	Logarithmic function		Quadratic function		Sq. root function		U.S. supply elasticity from direct regression	Approximate "expected" output

whether realistic supply functions can be derived from statistically fitted production functions according to the notion that a firm's supply curve is that portion of marginal cost above average cost.

Our results lend support to the position that derived supply equations are not empirically reliable. Specifically, our analysis suggests that:

A. Output predictions obtained from the derived supply approach do not exhibit a consistent magnitude or direction of bias—they range from slight under-estimates to extreme over-estimates of actual output, with the latter being the most prevalent.
B. Both casual observation and directly estimated supply equations show firms to be less responsive to price changes than indicated by supply elasticities derived from production functions.
C. Elasticities and output predictions based on derived supply functions appear over-sensitive to changes in the length of run.

Unacceptable results can be attributed to one or more of the following: (1) restrictions which the production function places upon the form of the supply function, (2) unrealistic assumptions of the derivation process, and (3) unreliable estimates of the production coefficients.

Selection of the proper type (form) of production function is important in supply derivation. Our findings support the belief that the logarithmic function in particular may lead to somewhat erroneous predictions if the sum of the production elasticities is larger than one-half. However, all or even most of the responsibility for the unrealistic elasticities and output predictions obtained in this analysis cannot be attributed to improper equation form. Moreover, it is not clear whether the remainder is due to unrealistic assumptions, or unreliable estimates of production coefficients, or both.

Obviously, the underlying assumptions of profit maximization, perfect knowledge, and unlimited quantities of variable resources are inconsistent with real-world conditions, and it would not be surprising if such simplifications contributed significantly to the unrealistic results. On the other hand, estimated production coefficients are often unreliable,[6] and derived supply equations are quite sensitive to any errors in these parameters. Even in those cases in which the estimated production coefficients seem to be highly significant and fit the data quite well, the predictive reliability of alternative production functions may vary substantially.[7] This suggests that the traditional tests of significance and correlation are not sufficient to establish the estimates as reliable representations of the true production relationships; thus, it might be useful for researchers empirically estimating production functions to routinely derive supply equations and compute optimum outputs and elasticities as another method of evaluating the production coefficients.

---

[6] Hildebrand's findings for the Cobb-Douglas production function suggest that "stability in the productivity estimates or even stable patterns is lacking" when changes in time periods, farm groupings, and treatment of inputs are considered [2, p.901].

[7] This is analogous to the situation reported by Stollsteimer and others in their efforts to obtain cost functions from cross-section data. They concluded that ". . . the

LARGE FARMS AND ABOVE PARITY RETURNS: INSEPARABLE OR JUST GOOD FRIENDS?

In 1967 the U. S. Department of Agriculture published the results of its study of parity returns as a measure of the well-being farmers [4]. Parity returns were defined as the "income required to make the current rate of return to the labor, capital, and management employed in farm production equal to the current rate of return to comparable resources employed in other sectors of the economy" [4, p. 9]. In this study it was noted that in 1966 only the larger farms, those with $20,000 or more value of sales, had returns from farming that exceeded parity returns. These results were obtained for each of four parity returns standards employed in the study—the landlord and stockholder standards, each computed with and without capital gains. None of the smaller farm size classes received returns that averaged as much as 100 percent of parity returns by any of the four standards. And the percentage of parity returns declined from the largest size class to the smallest. Other commentators on the farm sector seem to have interpreted this as implying that only the large farmers are getting above parity returns, and conversely, that the secret to receiving above parity returns is to achieve a large volume of gross sales [2, p. 195; 3, p. 18].

Since the figures on which the USDA study is based are averages of farms grouped by value of sales, it is subject to the question of interpretation: How do these averages relate to the individual farms that make up the population? A study of individual farm data in Michigan provides some indication of the relationships between average figures and parity returns for the individual farms that compose these aggregates [1]. Data from Michigan State University's Telfarm recordkeeping project for 1965 and 1966 were used. Parity returns were computed in a manner approximating the "landlord standard," excluding capital gains, as used in the USDA study.[1] To illustrate the conclusions from the Michigan study, the results from 378 dairy farms for 1966 are given in Table 1.

---

[1] The landlord standard assumes parity

Average data for the individual size classes showed the same general relationship as obtained by the USDA from the national data [Table 1, section I]. Class I farms, on the average, received returns from farming as a percentage of parity returns of 105 percent. This was the only size class to receive above parity returns and each successive class received a lower percentage of parity returns.

The quartile deviations associated with these median values indicate the wide range in parity returns received by the individual farms within each class. For example, while Michigan's class I dairy farms averaged above parity returns from farming in 1966, the actual percentages for the individual farms within one quartile deviation of the median ranged from 74 to 136 percent of parity returns. And the range for the median ± one quartile deviation for the class II farms was from 54 to 104 percent.

In order to see more clearly the degree of concentration, the proportion

---

returns to be the value of a rental return on equity capital, plus a wage for the farm operator and unpaid family labor equivalent to what the labor could earn in other occupations. While the procedures for determining equity capital and labor differed somewhat from the USDA study, it is felt that this would not significantly alter the conclusions reached here. For details on the computations see [1].

Table 1. U. S. and Michigan statistics on parity returns, 1966

Item		Size of farm (Gross sales)		
		$40,000 unit & over	$20,000–$39,999	$10,000–$19,999
I. Returns from farming as a percentage of parity returns:				
A. U. S. farms, average	Percent	129		85
B. Michigan dairy farms,				
average	Percent	105	81	42
median	Percent	105	79	43
Q.D.[1]	Percent	31	25	16
II. Percent of farms with above parity returns:				
A. Michigan dairy farms	Percent	52	34	3
B. Michigan, all other farm types	Percent	47	32	19
III. Return to operator labor for dairy farms with returns from farming:[2]				
A. Above parity returns	$/hr.	5.2[illegible]	3.70	2.78
B. Below parity returns	$/hr.	.3[illegible]	.92	.17

[1] Q.D. = quartile deviation = $\frac{\text{3rd quartile} - \text{1st quartile}}{2}$

Median ± Q.D. will include approximately one-half of all observations.

[2] Residual return to operator labor with capital charged at 5.5 percent and unpaid family labor valued at $1.91 per hour.

Source: U.S. data is from the U.S. Department of Agriculture [4, table 8]. Michigan data is computed from Telfarm records.

of farms with above parity incomes within each economic class was computed [Table 1, section II]. This shows that even among those farms selling $40,000 and more of products, only one-half of the individual farms earned parity returns or better although the entire group averaged 105 percent of parity returns. And while the class II dairy farms averaged but 81 percent of parity returns, one-third of the individual farms received above parity returns. Similar proportions for classes I and II farms were also observed for all farms of other types in the sample, along with a few in class III. These results suggest that a greater proportion, but by no means all, of class I farms earn above parity incomes, but such incomes are not restricted to the larger farms. While there is a substantial relationship between size of farm and the percentage of parity returns received from farming, size alone does not guarantee above parity returns.

Failure to receive farm income above parity returns on a large size farm does not necessarily mean an inadequate level of family income. A net farm income of, say, $20,000 would probably be considered adequate to support most families. But if this net farm income were only 50 percent of parity returns, it would seem to indicate a relatively inefficient operation. Conversely, operators on some of the smaller farms may receive above parity returns, yet find the income level inadequate to support a family and insufficient to allow for future growth of the farm operation.

In the final section of Table 1 are given the residual returns per hour to operator labor on Michigan's dairy farms when capital and unpaid family labor were imputed at the assumed opportunity costs of 5.5 percent and $1.91 per hour, respectively. The farms are divided into those receiving above and below parity returns. These rates can be thought of as the average wage rate necessary in a nonfarm job for the operator to be economically as well off as in farming. In this context, it appears that many farmers in the below parity group may be tempted to move to a nonfarm job, even at relatively low rates of pay. While these rates would differ from one farm type to another and from year to year, they do illustrate the differences in opportunity costs which may provide an incentive for various operators to leave farming. And these operators will come from large as well as small farms.

The above comments are intended to supplement, rather than dispute, the results set forth in the USDA study. But we do feel that they suggest a need for further investigation of the distribution of parity returns within each size class for the various types of farms. Such information may materially aid policy decisions with respect to the farm sector.

A LAWYER LOOKS AT WATER RESOURCE ECONOMISTS*

Water resource economists are somewhat unique among social scientists in that legal constraints on allocation and use of water make possible letter-perfect case studies which can ultimately result in the creation of policy. That is to say, water resource economists have the opportunity to help shape society's future by developing new systems of water law based on economic theory. This opportunity is not available to the same degree to other economists.

The dearth of specific proposals for legislative innovations suggests that water resource economists have not considered such recommendations as being within their province. Two potential roles exist for the economist interested in systems of water law. One, which is traditional, is merely to *identify* legal constraints; the other, seldom acted on, is to concentrate on *eliminating* such constraints.

A review of the literature supports this. Recognizing that history gives insight to strategies which in turn illuminate the mission pursued by water resource economists, I offer the following evidence.

The Tendency to Criticize. Criticisms of existing legal structures have been valid from the standpoint of economic theory. However, the very fact that such criticisms were not accompanied by constructive alternatives is evidence that economists traditionally have been interested only in constraint identification. Vague generalizations[1] are not constructive alternatives in the minds of those persons intimately involved with the legislative process. They would prefer concise proposals accompanied by detailed analyses of the results expected upon implementation.

Selecting the Proper Forum. The journals wherein water resource economists have published their research results are not the type which legislators are likely to read. To illustrate, one of the better interplays between law and economics appeared in the *Journal of Farm Economics* around the turn of the decade. But how many legislators or politicians read or were made aware of this interplay? Pathetically few, if any.

Selecting a forum in which to advance one's theories and hypotheses is relatively simple once the proponent has determined his major publication objective. Since it is difficult to find published research directed toward those concerned with the legislative

[1] Such as advocating the pursuit of water quality problems and allocation procedures on a regional basis.

process, one must wonder what objectives have been pursued by water resource economists. It can be argued that they are more interested in receiving the professional acclaim of their colleagues than in advancing society by improving legal institutions.

The Tendency to Ignore Political Feasibility. That a few economists have adopted the elimination of legal constraints as their mission can be argued by virtue of their pleas for a system of negotiable water rights. While the theoretical attainment of "highest and best use" is a laudable goal, it is significant that there has been no mad rush by state legislatures to adopt the system. Thus, one might cast aspersions on its political feasibility.

Rather than assuming or ignoring political feasibility, I submit that economists should recognize its significance and increase their usefulness to society by turning their creative talents to developing innovative legislative mechanisms which *approximate* the results of the purely competitive market system and which are palatable to legislators and other policy makers.

The Failure to Bridge the Communications Gap. There is another explanation for the paucity of states adopting negotiable water right systems. A communications gap exists between economists and legislators, caused in part by the failure to select the proper forum as discussed, *supra.* A contributing cause is the failure to recognize that economists have the burden of bridging this gap.

It is simply unrealistic to expect legislators to seek the opinion of economists (or the members of any profession) with respect to a given legal area, especially when they have not been made aware of existing deficiencies. Thus, those sincerely interested in seeing new and improved laws enacted must take the initiative in presenting and explaining their case to lawmakers.

Concluding Comments. Water resource economists can fill either of two missions: (1) constraint identification, or (2) constraint elimination. Historical evidence (mainly published research) indicates that economists have traditionally confined themselves to identifying legal constraints—and that primarily to members of their own profession.

In some cases, a firm's immediately critical constraint may be a specific legal rule. Eliminating this constraint will permit a movement toward the optimal point of production. Generally this movement will be accompanied by an increased benefit from our water resources.

Identifying legal constraints is a condition precedent to their elimination. However, it is the latter which is of greater benefit to society. Thus, if water resource economists are to accept a charge to maximize their usefulness to society, they should reorient their research efforts and adopt as their mission not only the identification, but also the complete elimination, of all legal constraints.

ECONOMETRICIANS AND THE DATA GAP: COMMENT

It has been said that, "if persons who oppose mathematical analysis thought of the economic world as one ruled by laws of mathematics and distribution theory, they would not object to mathematical formulations" [4, p. 137]. This is not necessarily so. For example, I have always been somewhat opposed to econometrics, not because of any preconception as to the nonmathematical nature of the economic world, but rather because, having worked with economic statistics all my professional life, I have a low opinion as to their quality in general, and think they are often unable to support the weight of econometric methods applied to them.

I am convinced, in other words, that some econometric model-builders fail to recognize that "the elaborate superstructures on many of their models rest on statistical data foundations of shifting sand—and not solid rock" [5, p. 413], as they hoped. Thus, while econometric methods may be able to "furnish scientific procedures for testing economic relations by experience" [4, p. 136], its results are nevertheless often awry simply because available statistics may be such an opaque glass through which to view "experience."[1]

Econometricians too often put the cart (intricate analysis) way out in front of the horse (reliable data). This was true when the Econometric Society was founded in 1930. In recent years, the horse has made much progress. But somehow, probably by main force and strength of econometricians' wishful thinking, the cart has stayed out in front and even lengthened its lead![2] The result has been some "important data gaps" [8, p. 1402], especially in the kind of detailed distributions, by size and by geographic area, which econometric models commonly require. Even where data *are* available, they are likely to be of poorer quality than is needed, but "the existence of error is too often ignored" [8, p. 1405]. And there may be an additional failure to recognize that, for use in econometric analysis, the data must be more accurate statistically and more refined conceptually than is usually necessary for other purposes.

---

[1] I do not wish to be recorded as being opposed to all agricultural econometric analysis. Two years' service on the Doctoral Theses Subcommittee of the AAEA Awards Committee has been a real eye opener in this regard. When a competent analyst finds suitable data relating to an important problem, the results are inevitably good—and *can* be outstanding. Unfortunately, I must also report that some good work in old-fashioned prose, well written and rigorously reasoned, has been unjustly downgraded simply because it lacked the currently fashionable mathematics appeal!

[2] Demands of statistics users *always* outrun data available. This is inevitable and is known as Grove's Law of Scarce Numbers. Its most unfortunate aspect, however, is that good men, not finding the data they had expected, waste their time and talents on research that is purely technique-oriented. If the problems of agricultural economics—and there are some big ones—are ever going to be solved, it is necessary for current research to be problem-oriented, not technique-oriented. This latter type of research is the ultimate in current uselessness because it solves no problem of the real world. In most cases, moreover, it is also the ultimate in longrun, absolute uselessness because data needed to make the new techniques operational are not only unavailable but likely *never* to become available.

In its frantic search for suitable data, the growing army of econometricians and would-be econometricians has often latched on to sets of data of very doubtful validity. Such dubious data may have been cooked up for other and more legitimate purposes, with no thought that they would ever be used in such a demanding type of analysis. But the budding econometrician is a most uncritical data user, quite capable of badgering producers of the data until they give him whatever they have just to shut him up. He then feeds the data into computers—many of which would stand idle if the "gigo[3] principle" were honored in anything but the breach.

A good, horrible example of recent vintage is the study by Scott and Heady [9] of regional demand for farm buildings, in which the dependent variable is expenditures on farm buildings, as estimated in the Farm Income Branch of ERS. The national series on farm building expenditures was concocted, on the flimsiest of bases [6, p. 18], as a legitimate device for calculating *depreciation* of farm buildings, to be used as a production expense. And national depreciation has been allocated directly to the states and regions in proportion to the value of buildings [6, p. 18], which is also legitimate. But Scott and Heady allocated annual estimates of *expenditures* on the *same* basis [9, p. 186], and then fed the resulting garbage into the uncomplaining computer.

The results of this study, it is important to note, seem entirely reasonable to the casual reader. Indeed, they must have seemed so to the editor of this Journal, for otherwise he could not have published them. So it is only my *personal* knowledge that the data used are garbage, plus a strict application of the "gigo principle," that has led to such an unfavorable conclusion. Something was radically wrong with the Scott-Heady study—but what?

Churchill Eisenhart has emphasized that "clear statements of the uncertainties of reported values are needed for their critical evaluation" [2, p. 1201], and he has also elaborated on the various kinds of situations that may arise. But he could not be expected to mention the situation where econometricians stubbornly refuse to recognize that data available are inadequate for their purpose,[4] as was the case with Scott and Heady—and probably with many other econometricians who have not been caught!

A principal conclusion of the farm buildings study was that the "overall coefficients for deflated gross income are positive . . . and all are significant at the 1-percent level. Although the absolute values of the coefficients for gross income are relatively small, this variable has the greatest influence on investment because of its relative magnitude and variance" [9, p.

---

[3] Garbage in, garbage out [1, p. 10]. S. S. Stevens, the Harvard psychophysicist, has said it more elegantly: "If something empirically useful is to emerge in the printout, something empirically meaningful must be programed for the input" [10, p. 849]. Stevens' article should be required reading for agricultural econometricians, for it would help to keep them humble, a consummation devoutly to be wished.

[4] Although he *does* mention a paper by L. M. Branscomb entitled, "The Misinformation Explosion! Is the Literature Worth Reviewing?" [2, p. 1204].

190]. But in the absence of any *real* information on expenditures for farm buildings, the national series has ordinarily been moved from one year to the next *in direct proportion to the change in gross income*. So we are impelled to ask: What have Scott and Heady discovered that is of any significance at all?

There is an important lesson here. Econometric methods are extremely powerful, and are quite capable of homogenizing, perfuming, and prettily packaging the worst kinds of data inputs.[5] And the rationalization of pure garbage is especially facilitated when various methods are tried in turn until one is found that works. Not only did Scott and Heady use inadequate data, they were also guilty of this trial-and-error type of malpractice.[6]

Agricultural econometricians are a special but proliferating breed who have come to believe that, since there is an obvious need for "hard, quantitative knowledge at all decision-making levels," there can be no excuse for its unavailability. Economic data are viewed as "observations generated by society," and if particular data are not to be found, obviously someone has been remiss in not recording them! In reality, of course, users of statistical data have acquired too much influence, for it is only *producers* "who know what the data are worth and what is involved" [11, p. 70] in their further development.

Statistical bricks are often made with little clay and less straw. Although seemingly solid to the casual observer, they will crumble under pressure—and only the brick maker knows this. For example, Arthur M. Okun told a Washington Statistical Society luncheon on March 13, 1968, that the United States has the best system of economic statistics in the world, so that he does not have to start an analysis by "forecasting the past," ignoring the fact that many, perhaps most, of our economic time series, now considered to be well established, got their start in just that way, and are not now, for their earlier years, nearly as accurate as is commonly supposed.

"We need restraint in using poor data, not just recognition of the need for good data while reaching for whatever numbers may be readily at hand" [3, p. 1593]. But since agricultural econometricians, whatever their other talents, have little talent for self-restraint, imposition of a professional code of ethics would seem to be the only solution. The first point in such a code would be that use of available data should not be "a reflex decision based on a burst of computation" [10, p. 854], but should instead be dependent on careful consideration, in a mood of thoughtful inquiry, of their adequacy for the purpose intended.

---

[5] Stevens made this point too: "Mathematics, like a computer, . . . will process any input, however devoid of scientific sense, and it will bedeck in formulas both the meaningful and the absurd. In the behavioral sciences, where the discernment for nonsense is perhaps less sharply honed than in the physical sciences, the vigil must remain especially alert against the intrusion of a defective theory merely because it carries a mathematical visa. An absurdity in full formularized attire may be more seductive than an absurdity undressed" [10, p. 853].

[6] For example: (1) "A stock variable . . . was not used for farm buildings because unsatisfactory results were previously obtained" (p. 188); (2) "Several nonlinear models also were formulated and estimated. . . . However, none . . . gave results as satisfactory . . . as those obtained by the linear model" (p. 188); (3) "The ratio of livestock income to total farm income lagged one year was tried as an explanatory variable but proved to be nonsignificant" (pp. 188–9); (4) "Farm size in acres, tried unsuccessfully as an explanatory variable, is highly correlated with the time-trend variable" (p. 190); (5) "Several formulations of income variables were used. Gross income divided by the index of prices received by farmers gave the best statistical results" (p. 191); and (6) "The ratio of gross livestock income to gross farm income was tried unsuccessfully as an explanatory variable" (p. 193).

The second point would be that relevance of the particular model chosen should be considered in the same thoughtful spirit, and in the light of the data selected as suitable. Once chosen, moreover, the model should be retained. If it proves unworkable, then the project should be abandoned, for the process of trial and error is likely to use up the equivalent of more "degrees of freedom" than are present in the first place.

The third and final point of an ethics code would be that all econometric models should be validated, like any intelligence or aptitude test, *before* publication. Validation means performance testing over a period of time —at least two years in most cases—to see if the model can actually do what it is supposed to do. This involves, as Olman Hee has pointed out, testing for the "predictability of statistical models" [7]. "There is an urgent need for more emphasis on performance testing" [7, p. 1479], an activity generally avoided by agricultural econometricians in the interest of early, and premature, publication.

If an ethics code like this had been strictly enforced over the last five years, the result would have been to eliminate, not just the article by Scott and Heady, but perhaps half the contents of this Journal!

ECONOMETRICIANS AND THE DATA GAP: REPLY

Perennially, or at least quadrennially, we econometricians must undergo absolution of our sins for thinking that the *amount* of change in economic variables as well as their direction of change would be desirable to know. Also, the omniscient tell us about the great unsolved economic problems of our time that we are sorely neglecting, with no indication as to what the problems are or how they are to be solved with only primeval tools.

It is interesting to note that—paraphrasing some of the comment—"What my company does is legitimate. What you do is illegitimate." The handbook Grove coauthored says the expenditures data come from sample surveys of expenditures and other sources of expenditures on farm buildings. It *does not* say they are spewed out by a number generator as a proportion of farm income. Additional *personal* contact with members of ERS (one of the authors of the article was an employee of ERS at the time) suggested the data were sufficiently good for econometric analysis. Apparently, Grove's *personal* knowledge is superior to our *personal* knowledge.

Also, the article was reviewed and approved for publication by ERS. But, of course, this is not the stamp of the Almighty himself, who hands down such revelations as Grove's Law of Scarce Numbers.

Farm building stocks and other questions slurred at in the comment were mentioned only briefly in the article, due to Journal space limitations. These and other findings are discussed more fully in Iowa State Research Bulletin 545, by the same authors.

Economists—even non-econometricians—rarely agree that there is only one model or one set of variables that is *the* model or *the* set for a particular economic relationship. Yet, in the name of chastity, the non-econometrician economist discards his own economic training when he castigates those who use the least cost mix (a larger amount of a low cost input-computer time and a lower amount of a high cost input-professional time) to investigate the relevant hypothesized models and variable sets.

Certainly, it would be a nice world if all data had no error; but lacking such a world, shall we turn back the clock to the 19th century, or do we do the best we can with what we have and go ahead from there? We opt for the latter!

CONVERTING PRICE SERIES OF INTERNATIONALLY TRADED COMMODITIES TO A COMMON CURRENCY PRIOR TO ESTIMATING NATIONAL SUPPLY AND DEMAND EQUATIONS*

In recent studies by Bjarnason [2], McGarry [3], and Schmitz [4], an algorithm for interregional trade developed by Takayama and Judge [5] and modified for international trade by Bawden [1] was used to predict international trade in feed grains, beef, and wheat, respectively. This algorithm makes it possible to determine equilibrium commodity prices, consumption, production, and trade flows for each of the trading nations under alternative policy assumptions.

The above approach to the study of international trade requires estimation of supply and demand equations for each of the major trading nations.[1] Furthermore, in order to obtain equilibrium solutions, all price series used in estimating national demand and supply equations must be converted to a common currency. In the studies listed, the United States dollar was chosen because it is the most widely used international currency. Thus, for example, equilibrium prices in the United Kingdom and Japan are in dollars per unit of quantity rather than in pound sterling or yen.

When each country's commodity prices are converted to a common currency prior to estimating supply and demand relationships, it is a simple matter to convert to dollars all of the price time series used for estimation, using yearly exchange rates. However, with the occurrence of any devaluation or appreciation of a country's currency, the authors found it best to use a base exchange rate for conversion purposes rather than yearly rates. They also found that when a deflator is used, the selected indices must have the same base year as that chosen for the base exchange rate.

There would be no objection to converting each country's annual price to United States dollars according to the then exchange rate if the so-called "purchasing power parity theory" were in reality perfectly valid. This theory states that the exchange rates move directly with real purchasing power in the trading nations of the world. Thus, for example, if the United Kingdom experiences some inflation in any given year while the United States does not, the real purchasing power of a unit of British currency will decline while the real purchasing power of a unit of American currency will remain constant. The exchange rates will then adjust to reflect this change in relative purchasing power of the two currencies; and the pound, in terms of dollars, will diminish in value. This theory obviously does not reflect international monetary reality, at least on a yearly basis. Despite the fact that relative purchasing power of the British and American currencies varied considerably in the

---

* The authors wish to thank Professors D. L. Bawden and R. E. Baldwin, University of Wisconsin, for their helpful comments.

[1] Point supply and demand estimations were made for other trading areas. It was also necessary to construct a matrix of transfer costs between each of the specified production and consumption centers.

18 years since 1949, for example, it was not until November, 1967, that the pound sterling was devalued to reflect the change.

Suppliers and purchasers of any given commodity, in making their production and consumption decisions, are primarily interested in the movements of prices in terms of their country's currency; that is, the absolute yearly movement in the price of the commodity and the relative movement in prices of other relevant commodities. Since the parity theory does not hold, these movements can be reflected by using a base exchange rate. This is because the direction and magnitude of price movements in any country considered, in terms of United States currency, will be the same as the real direction and magnitude of price movements in the country in terms of its own currency.

The need to select a base rate rather than yearly exchange rates in converting prices to United States dollars is illustrated in Figure 1, in which supply and demand equations for commodity X are represented. Assume the exchange rate of United States dollars to Canadian dollars to British pounds is 1:1:0.5. Prior to devaluation, Canada exports Q_1Q_2 units of commodity X (the distance Q_1Q_2 equals Q_5Q_6—United Kingdom imports) to the United Kingdom. This is represented by the difference between Canada's domestic and total demand—DD and D_1D_1, respectively. The export price of \$1.00 per unit equals £0.5.

Assume a Canadian currency devaluation in 1965 of 10 percent. The exchange ratio between United States, Canadian, and British currencies then become: 1:1.10:0.5 and Q_1Q_2 of X (the amount prior to devaluation) can be imported by the United Kingdom at £0.45 per bushel. However, devaluation causes the Canadian total demand curve to move to the right to $D'_1D'_1$, resulting in increased exports. A new equilibrium price of \$1.05, which equals £0.477 at the new exchange rate, is established.

The effect of the devaluation, *cet-*

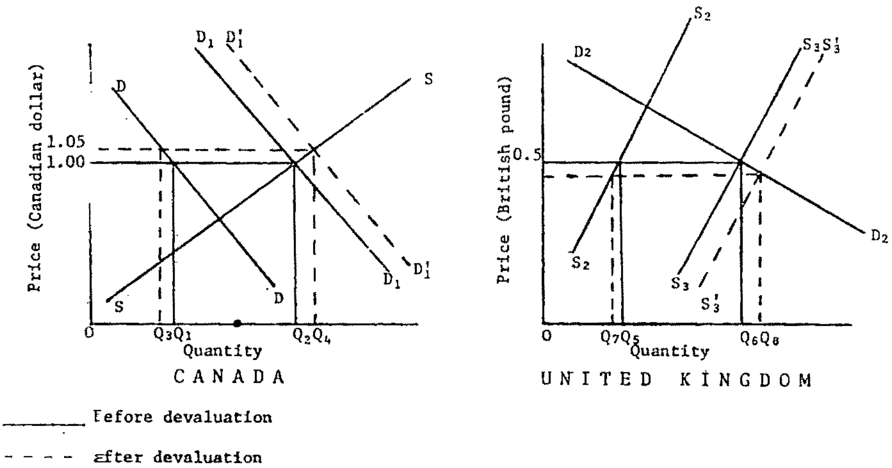

Figure 1. Devaluation and selection of exchange rates (transfer costs omitted)

eris paribus, causes Canadian production to increase from OQ_2 to OQ_4, domestic demand to decrease from OQ_1 to OQ_3, exports to increase from Q_1Q_2 to Q_3Q_4 (which equals United Kingdom imports Q_7Q_8), and the price of X to increase from \$1.00 to \$1.05 per unit.

Let us assume that Canada's supply and demand equations are estimated from time series data in which the last three price observations (1963-1965) are \$0.95, \$1.00, and \$1.05 per unit. Before estimation, these prices are converted to United States dollars. If the 1965 exchange rate (1:1.10:0.5) is used, the three prices become 86.4 cents, 90.9 cents, and 95.4 cents per unit. However, if yearly exchange rates are used, the price series becomes \$0.95, \$1.00, and \$0.945 per unit since the exchange rate prior to devaluation was 1:1:0.5. But this is not the series of prices observed by producers since this shows Canada's 1965 price to be lower than the actual 1965 price. In terms of its own currency, and thus from the standpoint of its producers and consumers, Canada's 1965 price of commodity X was higher than the 1964 price.

This analysis illustrates that, if devaluation or appreciation of a country's currency has occurred over the time period used as data for supply and demand estimation, a base exchange rate is required to convert the price series of the trading countries to United States dollars. In the example, only a base rate can reflect the increase in domestic prices in Canada for commodity X ensuing from devaluation.

A case may also be made for deflating all time series of prices used if some of the countries in the model have experienced considerable inflation. In any country where there is a fairly rapid rise in prices, producers will recognize that the real value of the currency is not increasing at as rapid a rate as money prices. In such cases, they will adjust their selling and purchasing habits to a more realistic level of commodity prices. However, if the decision to deflate prices is made, the selected indices used must have the same base year as that chosen in selecting the base exchange rate (1965, in the example above).[2]

In conclusion, one additional complexity is added to the vast array of those already encountered in statistical estimation of supply and demand responses for agricultural commodities. When dealing with internationally traded goods in the framework described at the outset, the supply and demand equations for each country need to be estimated, using price series which have to be converted to a common currency. With reference to the empirical studies alluded to, it was found that unless precaution is taken in selecting exchange rates and price deflators, the price and trade predictions are less than favorable.

EFFECTS OF NONPRICE VARIABLES UPON PARTICIPATION IN WATER-ORIENTED OUTDOOR RECREATION: COMMENT

A recent article in this *Journal* by Gillespie and Brewer [3] is susceptible to critical comment in several respects; it is deserving of commendation in others. Let me deal first with the latter category.

That the measurement of recreation demand is not a naive empirical "trick" remains to be proven to some economists—and to many noneconomists. It has been argued elsewhere that the treatment of recreation demand fits quite easily within the framework of general demand analysis [5]. The exact formulation of the demand model may vary with the research objectives, but the validity of including both price and "shifter" variables (income, age, education, etc.) is not in doubt. The Gillespie and Brewer attempt to obtain empirical estimates of the relationships between quantity and the various shifter variables is to be complimented—we know all too little about the magnitudes of these relationships.

On the other hand, the estimation of parameters in a model such as the authors describe would seem to be quite sensitive to model specification and to the extent to which the assumptions of the model are satisfied. In addition, the generality of the results would seem to be quite sensitive to the nature of the recreation activities and to the characteristics of the population. Along these lines, I should like to make four critical comments on the Gillespie-Brewer model and empirical results, and on their interpretation of the state of the arts in recreation demand measurement.

1. On the state of the arts, I would argue that the Hotelling-Clawson approach [2, 4] can easily be extended into a more general demand analysis by inclusion of relevant variables in addition to transfer costs [5]. Some of these variables, such as recreation quality, may be difficult to measure; nevertheless, a theoretical framework exists. Further, empirical estimates of price, income, and other parameters have been obtained in a number of studies, as, for example, in the Oregon salmon-steelhead study [1]. The Hotelling-Clawson model, I would argue, is a naive demand model in the sense that only quantity and proxy price

variables are included. It is not inconsistent with a more general demand model; rather, it is incompletely specified.

2. I am dubious of the validity of the Gillespie-Brewer assumption that prices were held constant by their procedure of sampling recreationists from a single "location," the St. Louis Metropolitan area. Their definition of the recreation area as a "vast rural mountainous area" implies that considerable differences in costs of travel may have existed within their sample of users.
3. To the extent that my second objection has validity, the parameter estimates are subject to biases in unknown directions. Even if my second objection has no validity, the lack of significance of four of the eight regression coefficients causes the elasticity estimates for income and age to be suspect. Considering the inherent problems of intercorrelation between the various non-price variables, one could be less critical of the empirical model if it were not presented as a predictive model capable of being generalized.
4. Although one objective of recreation research should be to strive for generality of results, I am not convinced that the present state of the arts is very far advanced toward this objective. Accordingly, the authors' claim for generality of their results should be viewed as a hypothesis rather than as a research result. The list of water-oriented outdoor recreation seems fairly inclusive, but no data are presented on the relative importance of the activities. More critically, the datum that 99 percent of the household heads in the survey were non-white can scarcely be consistent with the claim of a generalized predictive model. The present critic would be quite relieved to hear of a typographical error!

EFFECTS OF NONPRICE VARIABLES UPON PARTICIPATION IN WATER-ORIENTED OUTDOOR RECREATION: REPLY

We wish to compliment Stevens on his thorough reading of the article and his knowledge and understanding of some of the more difficult problems encountered in recreation research which are too often so easily passed over by other researchers.

We are aware of and in full agreement with Stevens on the sensitivity of which he speaks. However, we do believe that the assumptions of the model were sufficiently satisfied. Assumptions and comparisons can be made by judgments of an essentially ethical nature and, if so made, can be formalized into an equation. However, if research should wait until an overall accepted detailed set of judgments were made by the research universe, we would not go very far in explaining a great deal of economic and social phenomena.

We would still argue with the Hotelling-Clawson approach, primarily from the basic problem of adequately dealing with variables other than those directly or indirectly associated with price, as we suggested in our article. (The sample method used by Clawson in obtaining his data is also questionable.) Also, computing costs from the concentric circle idea leaves much to be desired. This, and the difficulty of obtaining reliable data, leads us to believe that the Hotelling-Clawson approach is not as easily extended (with reliability) as Stevens suggests.

To the second critical comment, the sample universe (St. Louis) is so small geographically that costs faced by each individual sample unit can be logically viewed as constant. If Stevens is telling us it is more expensive to travel greater distances or spend more time away from home, and that there is a difference in travel conveyance modes, we would definitely agree. But this is not the point in question. We were concerned with the cost function of a potential recreationist. To clarify our reply to the second criticism, we will briefly state the two assumptions made: (1) the distance between sample units within the universe used was so negligible that the difference was insignificant, and (2) there are hundreds of recreational points within the Ozarks area adjacent to the metropolitan sample area.

The prices faced by each and every sample unit to point A are the same, likewise to point B, C, ... We had no intention of inferring that prices relative to point A, say 20 miles distant, were the same as to point B, 250 miles distant, or that there was constancy in price A relative to B. We believe the criticism arises from misinterpretation and not from a fundamental difference. If this is the case, we are fully to blame for not being more explicit.

Stevens notes that the lack of significance of four of the eight regressions coefficients causes the elasticity estimates for income and age to be suspect. This we do not deny. In fact, we warned that they were subject to error but did give a degree of reliability. Regarding the level of significance of the variables, it is an arbitrary decision by the researcher as to what level of significance he wishes to set. Consumer preference studies normally accept a lower level of significance than other traditional type studies. No judgment is made whether this is good or bad. The socioeconomic characteristics were entered as linear, quadratic and cross-product variables. The decision was made to include a socio-economic characteristic (income) if it was significant in one function, and had a value of approximately unity in another function. We felt that the bias resulting from leaving it out of the model would be greater than that resulting from retaining the variable. Actually, this allows one to measure the total net effect of a socio-economic characteristic, rather than only part of its influence. It is implied that if all eight coefficients were significant then we would be permitted to generalize. Would we not be just a little guilty of generalizing that another sample taken would yield same results? There is always a chance that our one rejection of the null hypothesis was one of those included in the 5% error specified as Type I.

We also believe that one objective of research should be to strive for generality of results, as Stevens suggests, but whether or not any one piece of research advances the state of the arts is normally a value judgment and time is required for testing. The authors did not have in mind the converting of followers as a major purpose of the research; they were merely reporting the results they found in extensive research using a different approach than has been customary. Whether the reader prefers to view the results as a generality, i.e., an acceptable test of an hypothesis, or as an untested hypothesis, lies completely with him.

Stevens admitted the list of water-oriented outdoor recreation seems to be fairly complete, but objected to the fact that we did not present a relative importance scale. This was not the purpose of the article and would have had little value to what we were attempting to report. The preparation of a research report is now under way that will present this data in detail concerning the relative importance of various recreation activities and preferences of the population for those activities.

In conclusion, we would like to say that the figure showing 99 percent of the household heads as non-white is an error. The correct figure should have been 9.9 percent non-white. Also, the coefficient for labor should be +6.55, not −6.55, in Table I, page 86. These are typographical errors and we apologize for our carelessness.

ON DEFINING UNECONOMIC REGIONS OF THE PRODUCTION FUNCTION*

Discussions of symmetry of the three regions of production for a two-factor production function in economic theory texts often shed more confusion than light. The regions usually are defined implicitly or explicitly as follows:[1]

---

* The authors wish to thank their colleagues and the two *AJAE* reviewers for their helpful comments.

[1] See Leftwich [7, p. 115]. Most texts

1. In region I, the average product of the variable factor is increasing and the marginal product of the fixed factor is negative.
2. In region II, the average and marginal products of both factors are decreasing and both marginal products are positive.
3. In region III, the marginal product of the variable factor is negative and the average product of the fixed factor is increasing (to the left).

The border between regions I and II is usually shown to be where the average product of the variable factor is maximum (See Figure 1).[2] Regions I and III are symmetrical, and the border between regions II and III for the variable factor occurs at the point where the average product of the fixed factor is maximum and equals its marginal product. Stigler points out in a footnote that regions I and III are symmetrical only when the production function is homogeneous of the first degree.

How does one define region II for functions not homogeneous of degree 1? Bilas [1, p. 126] doesn't choose a definition but states that region II, "as *traditionally* defined, is relevant only to a production function that is homogeneous of the first degree. The important concept is that a firm will produce in the region in which *both* marginal products are positive. Whether they [*APP*'s] are increasing or decreasing is of little importance." (Italics and brackets are added.) Although there is a consensus concerning the "rational region" of production for functions homogeneous of degree 1, this topic is not discussed for other functions in most texts. More important, few students at this level understand *homogeneity* (constant elasticity of production), and many confuse it with *linearity* (constant returns to scale). Mundlak [9] showed that it was very important to understand homogeneity in order to understand the traditional definition of regions of production.

Mundlak [9] defined the regions of production for the two-input case in terms of the average and marginal productivities for functions that are homogeneous of any degree. Region II for Mundlak, as for Bilas, is the region where the marginal products of two inputs are each positive. However, he concluded that the procedure for defining regions for nonhomogeneous functions remains "an open subject."[3] The shortcomings of this definition of region II will be illustrated following the presentation of our cost-oriented definition.

---

refer to exceptions to symmetry of regions I and III in footnotes—or not at all. In addition to Leftwich's text, see, for example, Ferguson [4, p. 124]; Friedman [5, p. 130]; and Stigler [10, p. 126].

[2] The function used in plotting the curves in this note was

$$y = x_1^2 - 0.1x_1^3$$

which can be imagined to have come from the following function which is homogeneous of degree 1 in two inputs as follows:

$$y = \frac{x_1^2 x_2 - 0.1x_1^3}{x_2^2},$$

provided that $x_2 = 1$. It is easy to change the degree of this function. We substituted $x_2^{1.5}$ and $x_2^{2.5}$ for x_2^2 in the denominator to achieve the conditions imagined in Figures 3 and 4. See the note by Eichhorn [3] for an up-to-date view on the flexibility of the linear homogeneous production function.

[3] See Mundlak [9, p. 761].

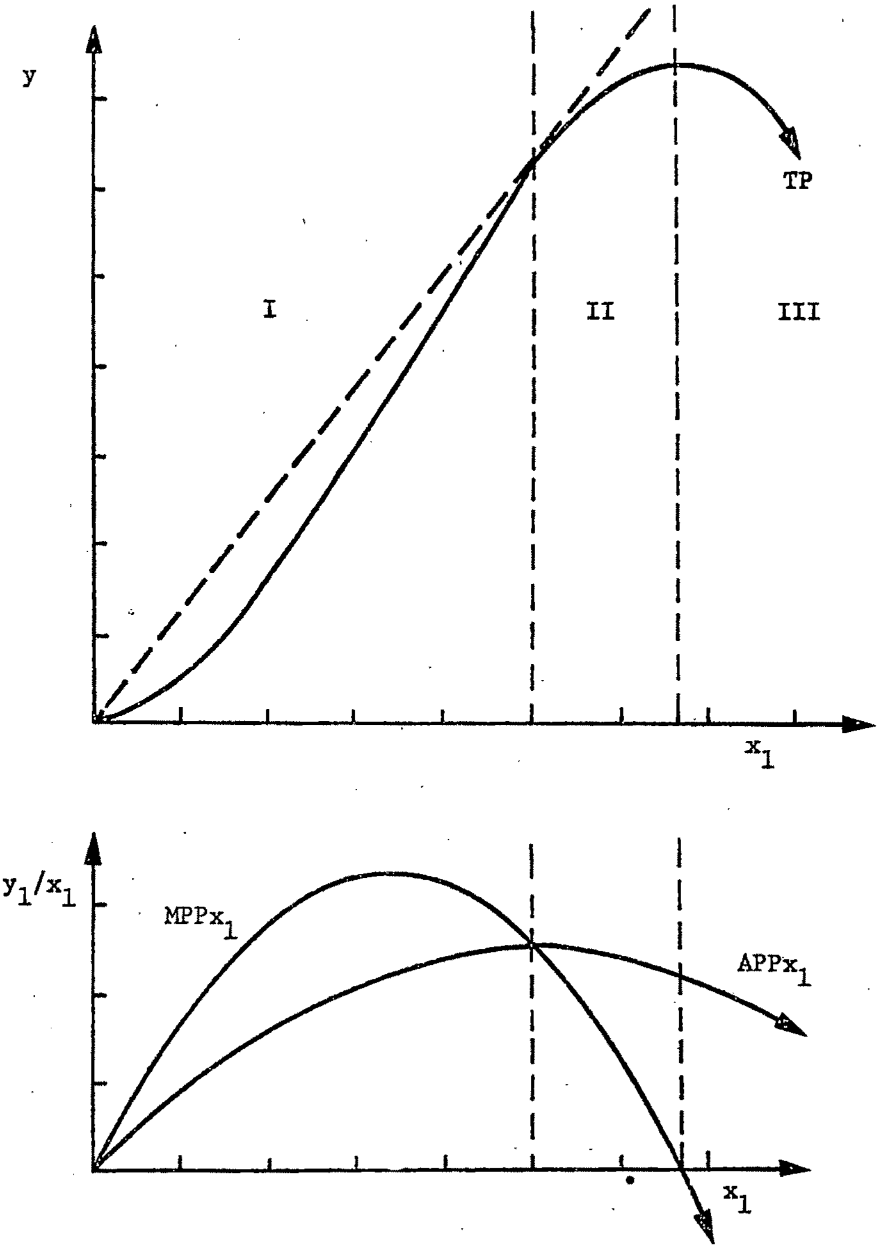

Figure 1. **Relationship between total product, average product, and marginal product based on a cubic production function for one variable input x_1 with all other inputs, $x_2, x_3, \ldots, x_n$ fixed in amount**

The purpose of this paper is to clarify two alternative definitions of uneconomic regions of production and to distinguish between the assumptions used as the basis for these definitions. One definition is based on the assumption of homogeneous production functions with two inputs. This might be called the "traditional" or "physical" or "constant elasticity" definition. The other is the cost-oriented definition used by Hicks [6] and others based only on the assumption of constant prices. The assumption of constant prices is much simpler, especially pedagogically, than that of homogeneity.

A Cost-Oriented Definition

The "intensive margin" of production presents no problem in teaching. A variable factor, x_1, if free, is liberally applied right out to the point where its marginal physical product, $MPPx_1$, is zero. This is the boundary between region II which is rational and region III which is uneconomic for all positive input prices.

It is with the "extensive margin," where the variable factor will be applied in at least a sufficiently high ratio to achieve maximum (or declining) average physical product, $APPx_1$, that problems arise. These problems can be simplified considerably by assuming constant prices and identifying the maximum point of $APPx_1$ with the minimum point of the average variable cost curve (in the single variable factor case).

In Figure 2, it is shown that if it is profitable to use any x_1 it will always be profitable to use x_1, at least to the point where $APPx_1$ is a maximum. This diagram shows total revenue, TR, as a function of one input, x_1. If the price of the product is constant, then TR has the same shape as the total product curve. If the input price is constant, total variable cost, $TVCx_1$, will be a straight line through the origin. The distance between TR and $TVCx_1$ represents net returns over the cost of x_1. Net returns with respect to this input will be maximized where $TVCx_1$ is parallel to TR.

At the price of x_1 represented by $TVCx_1$ in Figure 2, there are no profits. This is the point where $APPx_1$ is a maximum. For any lower price of x_1, a larger quantity of x_1 would be used. If the price of x_1 were higher than that represented by $TVCx_1$, no x_1 would be used. Hence, we can say that if it pays to use any x_1 at all, it pays to use it at or beyond the point where $APPx_1$ is maximum (and hence average variable cost increasing in the single variable input case).

There is no reason why this rule can't be extended to define rational use of each input for functions of more than two inputs. *The economic region of production is defined by a decreasing $APPx_i$ and a positive $MPPx_i$ for each input, x_i, while every other input is assumed to be constant.*

This rule is not limited to the case of two inputs, as are the definitions in terms of homogeneous production functions referred to above. Moreover it corresponds to the third condition of Hicks and Carlson.[4] Hicks' condition that the average cost be increasing is

---

[4] There is relatively little confusion concerning the rational region of production in a cost of output context. From a cost of output standpoint, profits in the competitive case are maximized where (1) $MC =$ price, (2) MC is increasing, and (3) average variable cost is increasing. See Friedman [5, pp. 107-111]. The corresponding average and marginal product conditions for inputs are stressed by Hicks [6, pp. 82 and 85] and Carlson [2, p. 100].

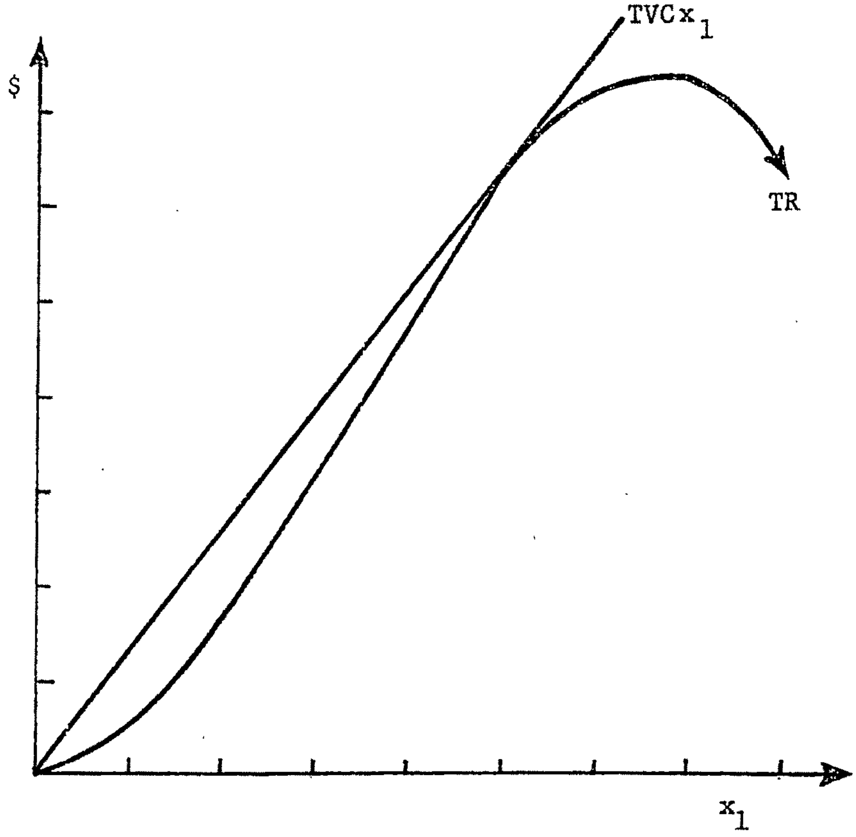

Figure 2. **Total revenue and total variable cost with respect to one variable input illustrating zero returns to the fixed factors,** $x_2, \ldots, x_n$

necessary for profit maximization and applies to any number of variable inputs or joint products. This condition states that a level of production which meets the first and second order conditions must also be superior to any other combination, including no production.

The result is different from that obtained by Mundlak [9].[5] For elasticities of production greater than one, his definition encompasses a larger region of rational production; and it is precisely in this case that his rule suggests that production could take place with *APP* increasing. The Mundlak approach will now be explained a bit more fully and the results compared with the above rule.

The Elasticity of Production Approach

The elasticity of production for a two-factor production function

$$y = f(x_1, x_2),$$

when the quantity of each factor is

---

[5] *Op. cit.*, [9, p. 758].

multiplied by a constant m, is given by the formula:

$$(1) \quad e_p = \frac{dy}{my} = \frac{MPPx_1}{APPx_1} + \frac{MPPx_2}{APPx_2}.$$[6]

This definition holds for all production functions, and for any given point on a function, it specifies that

$$\frac{MPPx_1}{APPx_1} = e_p$$

when $MPPx_2 = 0$.

Elasticity less than one

If $e_p = .5$, for example, what can be said about the relationship of $APPx_1$ to $MPPx_1$ at the point where $MPPx_2 = 0$? In this case, it follows from (1) that $APPx_1$ must be twice as large as $MPPx_1$ at this point. Since $MPPx_1$ is less than $APPx_1$, $APPx_1$ is decreasing. This relationship is shown in Figure 3.

Where does region II begin in Figure 3? If one follows the definitions of Mundlak and Bilas, region II begins where $MPPx_2$ becomes positive. Following the cost-oriented rule to produce in the region where the average product of x_1 is decreasing and the marginal product of x_2 is positive also means that one should use x_1 at least up to the point *IB* in Figure 3. If the elasticity of production is less than one, then, the two definitions of region I agree.

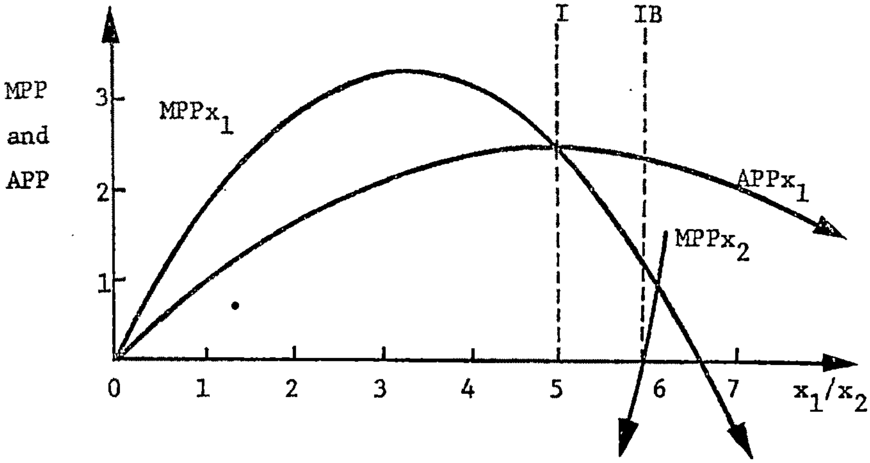

Figure 3. Relationship of $APPx_1$ and $MPPx_1$ when elasticity of production is less than one

---

[6] The definition is based only on an assumption of equi-proportional changes in all inputs that change, $dx_1 = mx_1$, $dx_2 = mx_2$, etc., and the mathematical expression for the total differential

$$dy = \frac{\partial y}{\partial x_1} dx_1 + \frac{\partial y}{\partial x_2} dx_2 + \cdots$$

or

$$dy = MPPx_1 mx_1 + MPPx_2 mx_2 + \cdots$$

Dividing by y gives us the proportional change in output and dividing further by m gives us the proportional change in output divided by the assumed scalewise proportional changes in all inputs that change, or the desired definition of elasticity. One convenient test for homogeneity is to show that e_p is a constant.

Elasticity constant and greater than one

If $e_p = 1.5$, then $MPPx_1$ is 1.5 times larger than $APPx_1$ at the point where $MPPx_2 = 0$. Since $MPPx_1$ is greater than $APPx_1$, $APPx_1$ is still increasing. This relationship is shown in Figure 4. In this case, should one define region II to begin at the point where $MPPx_2$ becomes positive, IA, or at the point where $APPx_1$ is maximum and average variable cost is minimum? Production between IA and I would not be economic if the prices of the product and x_1 are constant. It is our contention that it would be sounder economics to teach that the rational region of production begins where $APPx_i$ is maximum and ends where $MPPx_i$ is zero. These conditions must hold for all inputs.

Since $APPx_1$ and AVC are inversely related only in the single variable input case, what can be said when two or more inputs are variable? Whenever input proportions are constant, it is possible to treat all the inputs which change together as one composite input. Statements about elasticity of production greater than one for several inputs can be translated into *APP* increasing (and hence average variable cost decreasing) for the composite input. Starting with two conditions: (1) constant prices and (2) elasticity of production greater than one for all of the inputs which are varied together, profit maximization requires that output be expanded until one of these conditions gives way. Elasticity could become less than 1 (*APP* declining), input prices could increase, or the product price could decrease in order to limit production.[7] Carlson [2, p. 22] stressed this relationship graphically, and McElrow [8] has helped clarify the algebra of elasticity for any symmetric produc-

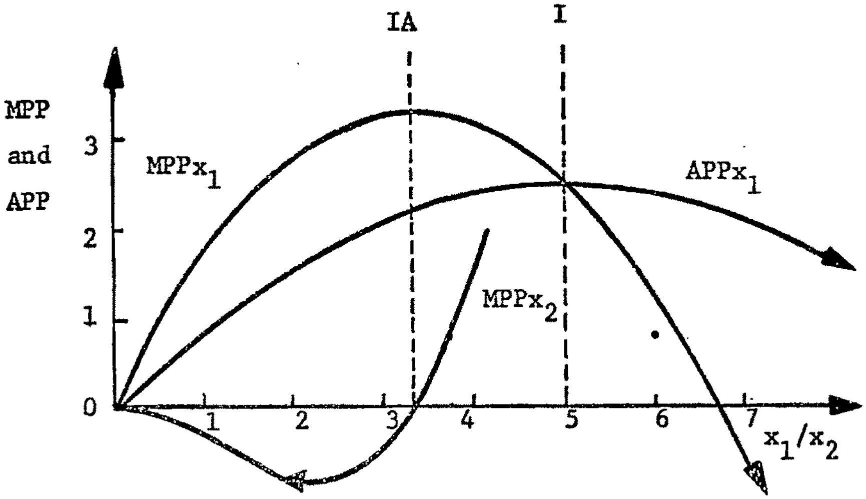

Figure 4. Relationship of $APPx_1$ and $MPPx_1$ when elasticity of production is greater than one

---

[7] Actually, the authors feel that costs of transporting inputs or products provide the most plausible upper limits on plant sizes.

tion function. When input proportions are not constant no simple connection between the elasticity of production and cost is possible.

Conclusion

There is something to be said for the esthetic properties of regions I, II, and III as defined in purely physical terms for two input production functions that are homogeneous of degree 1. Mundlak helped clarify this definition of the three regions of production and, at the same time, extended it to functions that are homogeneous of any degree. We have found his note very useful in our teaching.

Still, the authors feel that simplicity of assumptions and the need to think in terms of more than two inputs provide a strong case for a cost-oriented definition of the economic region of production. When input and product prices are positive and constant, region II is defined by $APPx_i$ decreasing and $MPPx_i$ positive. This rule applies to every input and every production function as long as prices are constant.[8] It is an unnecessary distraction to bring homogeneity and symmetry into our textbook discussions of the uneconomic regions of production.

J. A. SEAGRAVES

North Carolina State University

---

[8] Both *AJAE* reviewers asked that the discussion be extended to include variable prices. An increasing input supply function for a monopsony or decreasing product demand for a monopoly could cause optimal production to fall within region I as defined above for constant prices. It is much less likely that a decreasing input supply price function such as a rate schedule for an individual firm will cause optimum production to fall within region III.

ON TESTING COMPETING HYPOTHESES: ECONOMIC RATIONALITY VERSUS TRADITIONAL BEHAVIOR—A FURTHER DEVELOPMENT

At the 1967 Winter Meeting of the American Agricultural Economics Association, we presented a test for profit maximization.[1] We showed that in a profit-maximizing model, under certain assumptions, all pairs of relationships between variable inputs, output, and fixed inputs are linear in the logs. We tested this model for a random sample of owner-operated Greek farms. We found that the microcosm of our sample data is indeed characterized by such linear relationships between every pair of inputs, as well as between each input and output. Can we infer from this test that the entrepreneurs in our sample maximized profits?

Testing is a process of discriminating among competing hypotheses. A test by confirming a hypothesis rejects one or more alternative hypotheses—be it the null hypothesis, a naive hypothesis or a serious alternative hypothesis. In our case, a conceivable null hypothesis is that entrepreneurs behave in an entirely random way. Rejecting this hypothesis is hardly an impressive record for our test, as Professor Johnson justly observed in discussing our paper [5]. Moreover, Johnson suggested that the results of our test, the log-linear relationships between inputs and output, are consistent with the "traditional behavior" hypothesis in which "all Greek farmers were taught as young men to apply so much capital and so much labor per unit of land" [5, p. 398]. Our test, then, does not discriminate between the profit-maximization hypothesis and the "traditional" or fixed-proportions hypothesis.

Our present purpose is to develop the model that involves entrepreneurial profit maximization; to set up a perfectly respectable alternative hypothesis, which does not imply log-linear relationships between inputs and output and which, as a result, is rejected by the test; and to argue that "traditional behavior" as the term is used in the literature, is closer to the alternative hypothesis that we set up than to Johnson's alternative (naive) hypothesis of fixed proportions. In conclusion, we argue that the fact that our test does not discriminate between the profit-maximization hypothesis and Johnson's alternative hypothesis is hardly a defect of the test. Should one also wish to test for the fixed-proportions hypothesis, other tests are available—and the presently existing evidence suggests that the fixed-proportions hypothesis should be rejected for agriculture.

The General Model: Utility Maximization

Consider a general model in which utility is a function of revenues and costs. We call the objective *utility maximization*

$$\max U(R, C)$$

and we further specify the properties

$$\frac{\partial U}{\partial R} > 0 \quad \text{and} \quad \frac{\partial U}{\partial C} < 0.$$

Within this general model, we can specify a family of alternative hypotheses. Let us consider two: H_1, the "profit-maximization" hypothesis, and H_0, the "traditional" hypothesis.

$$H_1: \quad \max U(R, C) = R - C = \pi$$

with the properties

$$\frac{\partial U}{\partial R} = +1 > 0 \quad \text{and} \quad \frac{\partial U}{\partial C} = -1 < 0$$

i.e., constant marginal utility of revenue (or output) and constant marginal disutility of cost. Profit, π, is defined as the difference between revenue and cost.

---

[1] The paper has been abstracted in [9].

$$H_0: \quad \max U(R, C) = \log R - C = \tau$$

with the properties

$$\frac{\partial U}{\partial R} = \frac{1}{R} > 0 \quad \text{and} \quad \frac{\partial U}{\partial C} = -1 < 0$$

i.e., diminishing marginal utility of revenue (or output) and constant marginal disutility of cost. We will argue below that a perfectly acceptable definition of traditionalism involves the diminishing marginal utility of revenue as a necessary condition.

We make explicit the general *utility* maximization model by postulating a two-input Cobb-Douglas production function and constant elasticity functions for the supply of inputs and the demand for output.

$$(1) \quad Q_i = A_i f(K_i, L_i) = A_i K_i^{\alpha} L_i^{\beta}$$

$$(2) \quad K_i = k r_i^{\eta} \quad \text{or} \quad r_i = \left[\frac{K_i}{k}\right]^{1/\eta}$$

$$(3) \quad L_i = l w_i^{\epsilon} \quad \text{or} \quad w_i = \left[\frac{L_i}{l}\right]^{1/\epsilon}$$

$$(4) \quad Q_i = q p_i^{-\lambda} \quad \text{or} \quad p_i = \left[\frac{Q_i}{q}\right]^{-1/\lambda}$$

where: Q_i, K_i, and L_i are, respectively, physical output, capital, and labor for firm i; r_i, w_i, and p_i are, respectively, the prices of capital, labor, and output for firm i; A_i is the "efficiency parameter"; α and β are the elasticity coefficients of production and are assumed constant across firms; and η and ϵ are the supply elasticities for capital and labor, respectively, and λ is the demand elasticity for output—also constant across firms. Capital and labor are the two variable inputs of production that are within the control of the entrepreneur. All other factors of production (e.g., land, entrepreneurship, etc.) are lumped with the efficiency parameter and are considered fixed for a firm in the short run.[2]

We define the total revenue from output for firm i and by substitution from (1) and (4), we have

$$(5) \quad R_i = p_i Q_i = A_i' K_i^{\alpha(1-1/\lambda)} L_i^{\beta(1-1/\lambda)}$$

where $A_i' = q^{1/\lambda} A_i^{(1-1/\lambda)}$.

Similarly, we define costs for capital and labor for firm i and by substitution from (2) and (3), we have

$$(6) \quad \begin{aligned} C_k = r_i K_i &= \left[\frac{K_i}{k}\right]^{1/\eta} K_i \\ &= \left[\frac{1}{k}\right]^{1/\eta} K_i^{(1+1/\eta)} \end{aligned}$$

$$(7) \quad \begin{aligned} C_l = w_i L_i &= \left[\frac{L_i}{l}\right]^{1/\epsilon} L_i \\ &= \left[\frac{1}{l}\right]^{1/\epsilon} L_i^{(1+1/\epsilon)}. \end{aligned}$$

Within this general model, we can now distinguish between the two alternative hypotheses, H_1 and H_0.

The Profit-Maximization Model, H_1

We write

$$(8) \quad \begin{aligned} \pi_i &= R_i - r_i K_i - w_i L_i \\ \pi_i &= A_i' K_i^{\alpha(1-1/\lambda)} L_i^{\beta(1-1/\lambda)} \\ &\quad - \left[\frac{1}{k}\right]^{1/\eta} K_i^{(1+1/\eta)} \\ &\quad - \left[\frac{1}{l}\right]^{1/\epsilon} L_i^{(1+1/\epsilon)}. \end{aligned}$$

For profit maximization, we differentiate (8) partially with respect to each variable factor of production and we set $\partial\pi_i/\partial K_i = 0$ and $\partial\pi_i/\partial L_i = 0$. We have

$$\frac{2\pi_i}{\partial K_i} = \alpha\left[1 - \frac{1}{\lambda}\right]\frac{R_i}{K_i} - \left[1 + \frac{1}{\eta}\right] \cdot \left[\frac{1}{k}\right]^{1/\eta} K_i^{1/\eta} = 0$$

or

$$(9) \quad \log R_i = a + \left[1 + \frac{1}{\eta}\right] \log K_i$$

where

---

[2] Of course, as the subscript of the efficiency parameter indicates, the fixed factors may vary between firms.

$$a = \log \frac{\left[1 + \frac{1}{\eta}\right]}{\alpha\left[1 - \frac{1}{\lambda}\right]} \left[\frac{1}{k}\right]^{1/\eta}.$$

By symmetry, the maximization condition for labor input yields

$$(10) \quad \log R_i = b + \left[1 + \frac{1}{\epsilon}\right] \log L_i$$

where

$$b = \log \frac{\left[1 + \frac{1}{\epsilon}\right]}{\beta\left[1 - \frac{1}{\lambda}\right]} \left[\frac{1}{l}\right]^{1/\epsilon}.$$

Equations (9) and (10) indicate that in the profit-maximizing model, there is a systematic (linear in the logs) relationship between revenue (or output) and capital and between revenue and labor. The economic interpretation of these relationships is straightforward. Equation (9) describes the maximizing behavior of the firm that controls the quantity of capital it employs but has to take the quantity of labor as constant; and vice versa for labor in equation (10). Each of these conditions, taken by itself, is a necessary but not a sufficient condition for complete profit maximization. The two, taken together, are both necessary and sufficient conditions.[3]

From (9) and (10), we write

$$(11) \quad \log K_i = \frac{b - a}{\left[1 + \frac{1}{\eta}\right]} + \frac{\left[1 + \frac{1}{\epsilon}\right]}{\left[1 + \frac{1}{\eta}\right]} \log L_i.$$

This result indicates that in the profit-maximizing model, there is a systematic relationship between the quantity of capital and the quantity of labor employed.[4]

One can test to find out whether relationships (9), (10), and (11) are satisfied. We may illustrate how one can draw conclusions about profit maximization with reference to equation (11). In the case of perfect profit maximization with no random disturbances superimposed upon the systematic terms, the coefficient of correlation between the two variable inputs should tend to one. On the other extreme, if the systematic behavior dictated by profit maximization is entirely absent, only random disturbances would account for any relationship between capital and labor that might be observed, and the coefficient of correlation between the two inputs should approach zero.[5] Correlation close to one, then, confirms the hypothesis of profit maximization. Correlation close to zero rejects the hypothesis of profit maximization and confirms the hypothesis of random entrepreneurial behavior.

Suppose that the test reveals correlation close to one. The profit-maximization hypothesis is confirmed, but only in comparison to the random behavior hypothesis—an extremely naive hypothesis which is a sure loser. Is the victory of H_1 a Pyrrhic victory? It turns out that a more serious competitor, an entirely plausible alternative hypothesis, can be formulated and can be rejected by the results of a test that confirms H_1. This is the purpose of the next section.

---

[3] Formally, there is also a third partial condition for profit maximization—the factor-proportions condition. It refers to the firm that controls *both* capital and labor and has to achieve a specified level of output (irrespective of whether the scale of output is correct or not). This condition is described by equation (11).

[4] In the complete version of the paper, we also show that profit-maximizing output, capital, and labor are all log-linear functions of the exogenous efficiency parameter representing the fixed inputs of production (land, entrepreneurship, etc.), i.e., of A'_i in the above notation. As a result, firms that maximize profits do not all need to have the same factor proportions. See [8].

[5] The rigorous proof of this statement is provided in the complete paper. See [8].

The "Traditional" Model, H_0

We write

$$\tau_i = \log R_i - r_i K_i - w_i L_i$$

$$\tau_i = \log A_i' + \alpha\left[1 - \frac{1}{\lambda}\right] \log K_i + \beta\left[1 - \frac{1}{\lambda}\right] \log L_i - \left[\frac{1}{k}\right]^{1/\eta} K_i^{(1+1/\eta)} - \left[\frac{1}{l}\right]^{1/\epsilon} L_i^{(1+1/\epsilon)} = W(K_i, L_i). \tag{12}$$

We differentiate partially with respect to capital and labor, setting the first derivatives equal to zero. We have

$$\frac{\partial W}{\partial K_i} = \alpha\left[1 - \frac{1}{\lambda}\right]\frac{1}{K_i} - \left[1 + \frac{1}{\eta}\right]\left[\frac{1}{k}\right]^{1/\eta} K_i^{1/\eta} = 0$$

or

$$K_i = \left\{\alpha \frac{\left[1 - \frac{1}{\lambda}\right]}{\left[1 + \frac{1}{\eta}\right]} k^{1/\eta}\right\}^{(1/(1+1/\eta))}$$

$$\log K_i = \frac{1}{\left[1 + \frac{1}{\eta}\right]} + \log \alpha \frac{\left[1 - \frac{1}{\lambda}\right]}{\left[1 + \frac{1}{\eta}\right]} k^{1/\eta}. \tag{13}$$

By symmetry, the maximization condition for labor input yields

$$L_i = \left\{\beta \frac{\left[1 - \frac{1}{\lambda}\right]}{\left[1 + \frac{1}{\epsilon}\right]} l^{1/\epsilon}\right\}^{(1/(1+1/\epsilon))}$$

$$\log L_i = \frac{1}{\left[1 + \frac{1}{\epsilon}\right]} + \log \beta \frac{\left[1 - \frac{1}{\lambda}\right]}{\left[1 + \frac{1}{\epsilon}\right]} l^{1/\epsilon}. \tag{14}$$

This result indicates that in this "traditional" model, the systematic part of capital inputs does not vary with the systematic part of labor inputs, i.e., both are constant.[6] The variation, then, in each input is due entirely to random disturbances. As a result, we would expect the correlation between capital and labor to be rather small—in the extreme case, this correlation would approach zero. If, then, by fitting equation (11) we find correlation between capital and labor that tends to one, we conclude, not only that H_1 is confirmed, but also that H_0, this "traditional" hypothesis, is rejected.

Which "Traditional" Model?

We have, then, two "traditional" models, one suggested by us, which has been rejected by the finding of strong correlation between the logs of capital and labor, and one suggested by Johnson which is consistent with that finding. The purpose of this section is to argue that Johnson's hypothesis is weaker than the profit-maximization hypothesis, which is also consistent with the test; in fact, it can be rejected on the basis of prior information about agriculture. We also suggest that Johnson's model is a "pseudotraditional" model that is inconsistent with the concept of traditionnalism, as used in the literature.

Two are the characteristics of Johnson's traditional model: that knowledge has been handed down from father to son; and that this knowledge consists of fixed proportions. The way the knowedge is disseminated is surely an irrelevant criterion for characterizing economic behavior. Had the fathers taught their sons to maximize profit instead, this would not have made the profit-maximization model a traditional model. The fixed proportions characteristic of Johnson's model, on the other hand, is inconsistent with *a priori* information about agriculture. Fixed proportions implies zero elasticity of substitution. Although still sparse, the evidence presently available suggests that the elasticity of substitution in agriculture is consistently higher than one (1.2 is the modal coefficient given) [1, p. 240; 4, p. 963]. Furthermore, fixed proportions is a characteristic that is contrary to at least one formulation of the traditional model as it appears in the literature. The approach of technical dualism requires that the traditional sector displays variable technical coefficients of production; hence, it is able to absorb varying labor input. This is how the traditional sector becomes increasingly labor intensive as population increases between the fathers' and the sons' generation [3].

---

[6] From footnote 3, it also follows that capital and labor are constant functions of A'_i, the exogenous efficiency parameter.

In a recent article in this *Journal*, Marvin P. Miracle [6] has compiled a list of the criteria that are used in the literature, alone or in combination, to describe tradition (or subsistence) agriculture. They are: (a) "low" level of consumption, (b) "small" (or zero) proportion of production marketed, (c) "perverse" motivations to produce, and (d) slow rate of change of techniques of production. While Johnson's traditional model satisfies none of these criteria, our alternative traditional hypothesis is consistent with at least criteria (b) and (c).

The extreme case of variant (b) of traditionalism is that the economic units (family, in our case) are "... self-sufficient, producing only what they require for their own consumption, and having little or no systematic exchange relationship among each other" [7, pp. 43–44]. Lack of marketization implies that the marginal utility of own production declines rapidly with the marginal utility of own consumption. This diminishing marginal utility of production is the characteristic of our traditional model. Variant (c) of traditionalism emphasizes the "limited needs" of the economic unit[7] that curtail its motivations to produce. Limited needs also implies that the marginal utility of own production starts declining at an early stage. This variant is then also consistent with our traditional model.

Summary

A testable and empirical implication of a model in which farmers maximize profits is the existence of a log-linear relationship between the quantity of capital and the quantity of labor employed. This implication is inconsistent with the model in which farmers behave randomly. But most important, it is also inconsistent with a "traditional" model that is characterized by diminishing marginal utility of own production. Therefore, by confirming the profit-maximization hypothesis, we reject this traditional hypothesis.

The same empirical implication of the profit-maximization model is also consistent with the "pseudotraditional" model of fixed proportions. While the test that is built on the log-linear relationship between capital and labor is not sufficient to differentiate between the profit-maximization hypothesis and the "pseudotraditional" hypothesis, this is hardly a defect of the test. One can devise a good number of other alternative hypotheses that the test (*any* test, for that matter) cannot reject. However, one need not stop at this point in discriminating between the profit-maximizing and the "pseudotraditional" model. Auxiliary criteria, such as consistency with *a priori* knowledge about agriculture, can be used. And the presently available prior information is inconsistent with the fixed-proportions hypothesis.

---

[7] For an example of this variant, see [2].

ON TESTING COMPETING HYPOTHESES: ECONOMIC RATIONALITY VERSUS TRADITIONAL BEHAVIOR: REPLY

Professors Yotopoulos and Wise apparently agree with my earlier statement that their proposed test cannot distinguish between entrepreneurial behavior in a Cobb Douglas world and a fixed proportions world. In fact, they agree that any number of alternative behavioral specifications are consistent with their test. The purpose of a test is to discriminate among alternatives. In their original paper, they stressed the generality of their test. They now assert that the lack of discriminatory power in their test is no defect of the test. The logic of this assertion escapes me.

As I understand their original intent, it was to demonstrate that Greek peasant farmers are "rational," meaning they are profit maximizers. My misgivings with their treatment were in two categories. I could not find the rationale for a crucial assumption that allowed them to define a correlation coefficient as their rationality index. This problem I considered to be secondary to the basic problem that their proposed rationality index was also consistent with a fixed proportions model that does not contain profit maximizing behavior.

I interpret their current statement as postulating a new behavioral model, as they do not like the one I used. The dislike is understandable; I do not like it either, as a description of real world behavior. I did not then, have not since, and never will offer it as such a description. To show the ambiguity in their index, I thought only one counter example was needed. Fixed proportions as a production technique is a widely used analytical device, and as such, it seemed like a useful counter example. I believe my original reasoning is still valid. As long as behavior other than profit maximizing is consistent with their test, the identification of the test as one of rationality is subject to question.

Their new "traditional" model is a strange one, to say the least. They want farmers to maximize a utility function, $U = \log R - C$. For any plausible values of total revenue and total cost, the value of U is negative for this definition. As shown by their definitions, the marginal disutility of cost is always greater than the marginal utility of revenue, for plausible values again. I do not believe this specification can be taken too seriously as a "perfectly respectable" hypothesis, even if it does imply small correlation between a log of capital and the log of labor.

PAUL R. JOHNSON
North Carolina State University

ON TESTING COMPETING HYPOTHESES: ECONOMIC RATIONALITY VERSUS TRADITIONAL BEHAVIOR: REJOINDER

Professor Johnson, in his original discussion, raised two points: First, our definition of the "rationality index"—he considers it secondary and we agree. Moreover, we view this as a problem not sufficiently general and interesting to inflict upon the readership of this *Journal*, especially since it has been dealt with elsewhere. Second, a methodological problem—this is a point which is self-contained, almost entirely independent of our original paper, and also felicitous. He pointed out that testing is not only a process of matching hypotheses to the facts but also a process of discriminating among competing hypotheses. We had in competition three alternative hypotheses: profit-maximization, fixed-proportions, and random behavior. Our test rejected only the last one. Was that worth the effort?

The question that he posed was challenging. And we accepted the challenge. We formulated a perfectly respectable traditional hypothesis that has received currency in the literature. We consider it a true rival hypothesis, both to the profit-maximization and to the fixed-proportions hypotheses. Our test discriminates against this traditional hypothesis.

Up to this point, our disagreement with Johnson is whether our hypothesis is "strange" or not. In terms of the criteria set up in the literature, we have argued that it is not strange. The criterion advanced by Johnson (the value of U for "plausible" values of R and C) escapes us. Units are arbitrary and our results do not change if we specified the model instead as $U(R,C) = \log(aR) - (aC) = \log a + \log R - aC$. The important characteristic is that our model has a maximizing equilibrium: for, $0<R<1$, $\partial U/\partial R > -\partial U/\partial C$.

We do disagree, nevertheless, with the new methodological point that Johnson raises in his Reply: that a decent test is supposed to discriminate against all *but* one hypothesis. This is obviously impossible, since there exist an infinite number of alternative specifications that can be formulated so as to fit any set of observations; it takes only a polynomial with the turning points at the right places.

Still, however, the sifting and winnowing of competing hypotheses need not end with the results of any single test. More tests may further narrow the set of acceptable hypotheses. Also, as a last resort, the literature on economic methodology suggests auxiliary criteria for ranking hypotheses which are all consistent with the facts: the realism of the assumptions; the simplicity, fruitfulness, and elegance of the hypothesis; its consistency with other theory; etc. Our statement suggests that the fixed-proportions hypothesis could be rejected on the basis of other tests, as well as of one or more of these auxiliary criteria. And our conclusion is that the profit-maximization hypothesis does better on the basis of the presently available stock of facts and alternative hypotheses.

TRAINING FOREIGN GRADUATE STUDENTS IN AGRICULTURAL ECONOMICS: COMMENT

Professor A. B. Lewis [1] has written a very stimulating, constructive, and well documented paper on the increasingly important problem of providing *pertinent* and *useful* graduate level training to students from developing regions. The paper should provoke reactions from agricultural economists in "traditional countries."

Although I am in general agreement with the author's fundamental theory and aware that he states his argument primarily with reference to students from Asia and Africa attending United States universities, still there are two aspects of his paper about which I would like to comment, as they may relate to students from Latin America.

Lewis delves into philosophical and cultural traits to explain in detail and to show the professional limitations of students from developing regions attending American universities to do abstract thinking, as compared with American students. These limitations arise in Lewis' opinion "out of differences in habits of thought and views of reality, and out of differences in their concepts of human relationships and the functions and responsibilities of the scholar, the official, and the economic leader" [1, p. 685]. The author contends that the root of the problem lies in the difference between a "Greek" and a "non-Greek" mind.

Is the philosophical legacy of the Latin American student in United States universities "non-Greek"? Professor Lewis says yes. I believe Latin America is part of the Western world. As such, the "Greek mind" is part of our tradition and should be part of the Latin American way of thinking. Yet, I find some, but not all, of Lewis' characteristics of traditional agricultural civilizations applicable to students from the region. The Latin American student is strongly inclined to the literary style and to dialectics; and he tends to appraise problems and situations too subjectively. I cannot but agree heartily with the author when he talks about the "once and for all" remedies to all of our maladies and tribulations that are concocted by political leaders and scholars. In Latin America we have had, to name a few, industrialization, land reform, and, more recently, a Latin American Common Market. This last with the prodding, assistance, and support of United States leaders!

Why is this so? Perhaps the causes of these traits are to be found in institutional factors along with other influences of the "Latin endowment."

Not saying that he intended to imply a priority, Lewis lists and discusses nine quite orthodox course categories—farm management, marketing, farm finance, cooperation, land economics, agricultural prices, etc. These suggestions reveal his wide experience with problems and conditions in "traditional countries." My differences with Professor Lewis on his list are not so much of substance as of emphasis and omission.

Of the subjects listed, I would place agricultural prices last. Such a course, although important and necessary for a graduate student, does not have the utility in my part of the underdeveloped world that it may have elsewhere. Besides, the refinement and sophistication required to build price indexes and the lack of statistical series that are hard to find, preclude the construction and application of such planning and development aids for some time in the future.

I fully agree with Lewis' statement that farm management "is the most vital subject for foreign students to master because it is a necessary foundation for all economic judgments affecting both individual farm operations and the entire farming sector." He further adds that this course, when taught to foreign students, should not be done mechanically or superficially but that the reasons and the depths of it ought to be explored and explained. Lewis could have added for emphasis that our concept of a farm is clouded by the tens of thousands of small subsistence farms with the familiar characteristics of low productivity, inefficient resource use and "traditional" production methods. Understandably, when faced with the task of budgeting an American farm as part of a farm management course, we are literally at a loss on how to proceed. This kind of training, as it is usually offered, is of limited value. Further, few of us have had equal or even similar experiences in our countries. Farms, large or small, have different crops and different enterprise combinations; levels and utilization of technology and entrepreneurial attitudes and values also differ.

To Professor Lewis' list of desirable courses for students from underdeveloped areas, I would like to add logic, agricultural policy, and research training. If the Latin American student lacks a "Greek mind," the enumeration by Professor Lewis of what has been inherited from Greek thinkers logically leads us to consider logic a needed course for students from developing countries. Most of the students from traditional countries, when they return to their homeland, occupy positions from which they can either formulate or influence policy. Very few Latin American countries have an articulate, clearly defined and stated policy in agriculture. Students should be exposed to the philosophy and practical difficulties and limitations of policy. Such a course lends itself admirably to impressing upon the foreign student the futility of pursuing panaceas.

I am sure Professor Lewis is well aware that research is one of the most rewarding activities most returning graduate students have to perform. He is also keenly aware of the need for research in order to provide information and guidelines for formulating policy and planning the development of agriculture. This aspect, training in research, its theoretical, philosophical, and empirical conception and application, is one in which United States universities could make a significant contribution to developing regions. The student needs to learn how to integrate theory with reality. He needs to be trained to recognize the problem at hand; to state it clearly and precisely; to limit the scope of the study; to "see" and discover the implications and projections of the data he gathers; and to give the collected data a realistic and comprehensive analysis and interpretation. Because of inadequate training in research for conditions prevalent in developing regions, a good number of research reports by Latin American students with postgraduate training lack the scientific rigor they could have and, thus, the usefulness that the region so urgently needs.

Reviews

Buchanan, James M., *The Demand and Supply of Public Goods*, Chicago, Rand McNally and Company, 1968, ix + 214 pp. ($5.00)

During the last quarter of this century, as the exigencies of military preparedness and economic development increased the economic importance of the public sector in both developed and less developed nations, and as a new affluence in advanced countries allowed the luxury of thinking about human welfare and the quality of life, economists finally began to invest a good portion of their energies on problems not readily answerable in the terms of Marshallian diagrams or Keynesian graphics. James M. Buchanan's theoretical treatise on the supply and demand of public goods is both evidence of and an integral part of these new investments of our profession. It is an important book; more, however, for the profoundness of the questions it raises than for those it lays to rest. Building upon, as well as synthesizing in a unique way, the works of such Engish speaking scholars as R. A. Musgrave, Paul Samuelson, and J. G. Head, Buchanan develops the foundation for a new approach to public finance. Critical of the fact that in the past the theory of public finance has treated government as an exogenous factor "wholly apart from their citizens" and has limited its concerns to the problem of how to most effectively cater to governmental needs for resources, Buchanan sketches a new course for this subdiscipline of economics. He wishes to see a theory of public finance that yields both positive and normative insights into the demand for and the supply of public goods and the institutional foundations necessary for the proper and adequate expression of this demand and supply. His book is an attempt to begin the structure of such a theory.

Professor Buchanan's approach to model building is standard. Assuming away all the complexities of reality, he constructs a humorous and informative simple exchange model, "one in which there are only two persons (perfect equals) and two goods, one public and one private." He established the conditions for equilibrium in this model with ease. In fact, he does it in three different ways: a modified Edgeworth diagram, an algebraic formulation and Marshallian geometry. But as soon as he complicates his model through relaxation of his assumptions, he moves rapidly towards a world of difficulty founded on, all too often, completely elusive equilibrium conditions. And herein lies the major weakness of the book.

The complexity and uncertainty of the deductions obtained from his models may be indicative of the shortcomings of the methodology he follows. Though he wishes to move beyond the simple application of Marshallian based systems, he ties himself to the methods of standard economic analysis. He still employs the comfortable apparatus of assumptions, equations, and deductions which, unfortunately, are ultimately more revealing of the importance of omitted variables than of the variables included. Professor Buchanan might have been better off asking if perhaps the questions raised by the desire for public goods are intractable when approached in terms of indifference maps and the avoidance of interpersonal comparisons this methodology demands. What is necessary is a broader approach to the subjects of institutional arrangements and value systems than mathematical systems seem to allow us to follow.

Buchanan's theoretical models are not difficult and are well worth working through. But it is when Buchanan departs from the world of curves and formulas that the reader receives his greatest value. His discussion of the "free rider problem"—individuals who, when they apply the logic of maximization of expected values, receive the benefit of public goods without sharing the cost incurred in their supply should be exceptionally interesting to all concerned with the problem and benefits of social insurance. And his discussions of: the organization of institutional arrangements; the enforcements of necessary patterns of behavior; unanimity rules; rules for reaching group decisions; institutions of fiscal choice; which goods should be public and which private; cause the reader to reflect not only upon the daily headlines but upon the foundations of our discipline and those of social science.

For those who have not followed the literature in this field or have not done so with maximum efficiency, Buchanan supplies excellent bibliographical information at the conclusion of most chapters. This is an important element in the book, for it is difficult to visualize a concerned reader who will not wish to delve more deeply into the literature.

•

Burk, Marguerite C., ***Consumption Economics: A Multidisciplinary Approach,*** **New York, John Wiley & Sons Inc., 1968, xvii + 359 pp. ($9.95)**

One would almost have to agree with Dr. Burk that "the chaotic combination of masses of data, many problems, and relatively little economic theory has made the field of consumption economics appear far more diffuse and insignificant than its rapid development and substantial contributions to agriculture, business and government policy and program determination merit." With breadth of purpose, meticulous attention to detail and a meritorius attempt to show interrelationships between economics and related fields such as marketing, psychology, social-psychology, and others, Professor Burk has done great service; however, the book leaves the impression that the author still is not clearly delineating the field from, say, marketing on the one hand and welfare economics on the other. In spite of this, the book is a very substantial contribution which should be especially useful as supplementary or prime text material in Food Economics, Agricultural Policy, Price Analysis, Marketing, and related courses, as well as in Consumption Economics courses *per se*, at the upper division and beginning graduate levels.

Professor Burke devotes the first part of her book to a discussion of "What is Consumption Economics." In the four chapters making up this section, she tackles with vigor the scope and content of consumption economics and the role of consumption in a market economy, as well as an historical view of levels of consumption in the U.S. and consumption in less-developed countries. In this, Professor Burk seems to have a hard time positioning herself in relation to her readers; it seems as if she is alternately writing for students (as professed in her prefatory comments), practitioners such as marketing personnel, and fellow academicians. Thus, it is hard to know from what vantage point to react or evaluate. Also, the level of complexity seems to vary—for instance, she drops in a concept such as comparative advantage quite cavalierly while seeming to start nearly from scratch in development of other economic concepts, assuming little by way of reader cognizance. While some authorities on economic development might feel she over-simplifies problems of development, it seems to me she threads through the discussion of consumption in less-developed countries (Chapter 4) insights of great depth and crucial relevance and, furthermore, couches them in direct, penetrating terms. Less conclusive, in this reviewer's mind, is her delineation of the field of consumption economics. And, although her concern for greater collaboration among economists and other social scientists seems well grounded, it may be that she belabors this point in her discussion of elementary concepts from the various social sciences as if social scientists had no acquaintance beyond their own discipline. Getting them (us!) to actively engage in cross-disciplinary activities is another matter, but some acquaintance with elementary principles of various social sciences might logically be assumed.

Part II Professor Burk devotes to the microeconomics of consumption. Chapter 5, "Marketing and Behavioral Science Approaches to Study of Consumer Behavior," is a useful and succinct review of psychological, sociological, and anthropological concepts having meaning for understanding consumption. In Chapter 6, "Elementary Economic Theory Relative to Consumer Behavior," she makes serious . . . and probably viable . . . accusations against economists for their over-simplifications; yet, she, too, seems to slip into their habits . . . she omits explicit reference to time periods when discussing the concept of utility, for example. In other chapters, most particularly in Chapter 10, in proposing a conceptual framework for the analysis of the micro structure of consumption, it strikes me that Dr. Burk makes a useful contribution; but at the same time

I wish she would have more fully integrated the concepts she is attempting to synthesize (either from the student's, practioner's, or academician's point of view).

Professor Burk deals with the macroeconomics o consumption in Part III. This section is useful, but seems uneven in its treatment, especially Chapter 16. In this section, her economics might be criticized where she confuses variable proportions with returns to scale [p. 225]. More minor criticisms are her uses of terms such as frequency distributions, continuous variables, and others, without explanation, which might cause student hang-ups, especially for undergraduates. Also, Dr. Burk, along with many others, errs in constantly referring to "the war" as a time benchmark . . . most students who are likely to use this book would have been born during or after the Korean conflict and would have matured during the Vietnam holocaust and, therefore, could hardly place World War II as "the war."

Throughout, and with some validity because of the greater abundance of data, Dr. Burk leans heavily toward agricultural examples.

Her two appendices appear to be extremely useful to researchers, both seasoned and beginning. Probably they would be relatively little used by the general student, especially undergraduate. Her usual completeness is shown by inclusion of a sectioned bibliography and both a name index and an unusually good and detailed subject index.

GORDON E. BIVENS
University of Missouri

Collins, Norman R., and Lee E. Preston, *Concentration and Price-Cost Margins in Manufacturing Industries*, Berkeley, University of California Press, 1968, 163 pp. ($5.75)

Students of applied economics will find in this book an excellent model for research procedure and reporting. The analysis utilizes previous research, carefully analyzes new data in light of economic theory, integrates the previous results with the new findings, and reports the conclusions in a concise and highly readable form.

The purpose and scope of the study can best be illustrated by quoting the hypothesis under examination: "Interindustry differences in the relationship between revenues and costs will be positively associated with the degree of oligopoly, as reflected in a concentration index, when differences in capital requirements and the relative importance of regional versus national markets are taken into account" [p. 12]. The primary focus is clearly on the relationship of profits to concentration, with geographic dispersion and capital introduced only because they are important intervening variables.

Collins and Preston begin their empirical investigation with a thorough review of the literature, including recalculation of relationships reported in earlier studies to make them comparable with the approach used in this study. Previous studies include those by Bain, Levinson, Fuchs, Weiss, Schwartzman, Stigler, and Sherman. Twenty two-digit (SIC classification) major manufacturing industry groups are then analyzed using Census data. A price-cost margin variable is defined as the difference between gross revenues and direct costs expressed as a percentage of gross revenues. This profit measure, along with the more typical measures, is then related to the degree of concentration. Since the several profit variables are highly correlated and yield similar statistical results, a theoretical preference for the price-cost margin variable is decisive in its being chosen for the more detailed investigation of the four-digit industries. Next, 288 of the 4-digit industries are examined, with 213 classified into ten industry groups for detailed study. For six of the ten groups, a statistically significant relationship exists between concentration and margin. Of the other four industry groups, the sign is usually correct but the coefficient is not statistically significant at the usual probability levels.

The results are consistent with earlier studies in indicating a positive relationship between concentration and profits. The indicated relationship is linear and continuous rather than kinked at any particular level of concentration. Yet, the relationship is far from exact, suggesting that other variables are of substantial importance in explaining price-cost margins. Several of these variables are discussed in the concluding chapter.

Several remarks might be made concerning the statistical procedures. The construction of the geographic dispersion variable is described but no justification is given for expecting a linear relationship between a constructed index of geographic dispersions and the price-cost margin. Admittedly, there is little basis for specifying any relationship other than a linear one. But, careful examination of the residuals plotted against the geographic dispersion index might suggest a functional form different from the linear form. Alternatively, one might search for a more meaningful measure of dispersion, one that might be related in a nearly linear fashion to price-cost margins. Similarly, data problems plague the estimation of a coefficient for the capital-output ratio. The ratio of book value of assets to value of shipments was used. Obviously, there is a sizeable measurement error in using this ratio as a valid indicator of the importance of capital in contributing to the price-cost margin. Such measurement errors bias toward zero the associated coefficient and reduce R^2 but probably do not seriously affect the regression coefficient associated with the concentration variable.

One would hope for a discussion of the relationship between *changes* in concentration and *changes* in profit margins. This relationship would be more meaningful in policy context where one is attempting to control concentration. In other words, to what extent are the relationships which emerge from a cross-section study appropriate in predicting dynamic changes within an industry? The authors are careful to say "*If* our cross sectional results can be projected into a time dimension . . ." [p. 115, emphasis added]. Users of their results should ask themselves about the reasonableness of this "if" statement. Those who reject the "if" statement are challenged to construct a dynamic model that will be useful in a policy context. Construction of such a model will be difficult because of the large number of intervening variables that merit consideration.

There are surprisingly few misprints but some readers may be confused on p. 78 where the signs of residuals are reversed in the text.

Collins and Preston have produced an excellent study. Their work presents a challenge to those who disagree to produce a more convincing argument.

LESTER V. MANDERSCHEID
Michigan State University

Dubov, Irving, ed., *Contemporary Agricultural Marketing*, Knoxville, The University of Tennessee Press, 1968, x + 270 pp. ($5.95)

This book is a collection of papers presented at the Marketing Section sessions of the Sixty-first Annual Convention of the Association of Southern Agricultural Workers in 1964. It consists of 15 papers and 12 discussions. I frankly do not know how to review the book. It is rather like being asked to review half of the proceedings issues of one of the recent annual meetings of the Association. When I discovered what I had accepted as an assignment—which was, of course, not evident from the title of the book—I felt put upon. But I shouldn't have. I found most of the papers interesting and/or instructive. If these papers are representative of the usual offerings at this conference, then I am put out for never being invited. It is evident the marketing economists of the South are concerned with the same issues as marketing economists in the rest of the country. Except for a tendency to select cotton and citrus as examples, the book shows little regional emphasis. I was, in fact, disappointed to learn so little of the specific issues related to the South. Of course, the title is misleading, for it implies a more comprehensive treatment than is delivered. A discussion of some issues in contemporary agricultural marketing economics is more descriptive of the content.

Let me briefly identify the content of the book. Part I is called "Background Issues." W. B. Back discusses "Relevant Questions for Agricultural Economics Research." He is concerned with the relevance of our research. His test of research results is the degree to which they provide perceptions of the future, especially as related to estimating the economic consequences of alternative programs, policies, or institutions. He wants more macro emphasis. His heart seems to be in the right place. H. F. Breimyer presents some interesting insights on the relationship of policy and entrepreneurial freedom in agriculture. W. W. McPherson tells us of institutional factors in economic development, with most of the emphasis on a comparison of U.S. and Latin America. I believe he is looking in the right place but is required to deal too briefly with a complex topic.

Part II is labeled "Emerging Problem Areas" and might better be "'Some things we have been thinking about lately." J. L. Knetsch talks of research on marketing recreational services which are natural resource based. I was especially pleased that he did not identify user studies of a zero priced service as studies of demand as has so often been implied. B. T. Lanham discusses his paper. M. L. Fowler analyzes problems of the price support program in cotton. He is appropriately concerned with the effect of policies designed to exploit situations where supply and demand are inelastic in the short run and much more elastic in the longer run. Neither Fowler nor his discussant, R. F. Anderson, deals with the problems of large number of people losing a means of support through the effects of technology and government programs in cotton.

E. D. Smith has a paper on the procedural problems of farmer cooperatives, which is discussed by J. M. Law. Smith seems to argue that until a variety of internal procedural problems of cooperatives are solved, voluntary groups are not likely to be effective in achieving market advantage for farmers.

I suppose no conference of this type would be complete without a paper on coordinating research and extension. J. C. Williamson provides a better-than-average contribution on this topic by emphasizing the truth of Adam Smith's observations of the advantage of specialization and coordination. A. D. Seale, in his discussion, reminds us that the Southern Marketing Research Committee developed a framework statement presenting a unified approach to coordination of marketing extension and research.

A. W. Woodard deals with extension assistance to processing firms in evaluation of alternative investment opportunities, and D. G. Dalrymple adds to the paper in his discussion. W. F. Williams has an insightful paper on market structure research, and P. E. Nelson deals with the relationship of macro-micro or firm management-market structure research. The problems raised by these papers are important ones. These papers are discussed by W. R. Henry and S. P. Parry.

Part III is called "Methodological Developments." The papers are fairly technical and empirical. They illustrate the application of several significant quantitative techniques to problems which are generally not trivial. The following papers and discussions are included:

An Analytical and Operational Framework for Solving Problems of Plant Location, by L. Polopolus; discussed by J. M. Stepp.

Use of Linear Programming for Obtaining Minimum Absolute-Deviation Estimates of Functional Relationships, by J. Havlicek, Jr.; discussed by T. E. Tramel.

Decision-Making Models: Methodology and an Application to the Poultry Industry, by J. R. Tedford; discussed by V. G. Hurt.

Generalized Distribution Problem: Framework and Application, by R. L. Feltner and D. D. Rohdy; discussed by B. R. Hoffnar.

Predicting Yields by Objective Counts and Measurements, by W. E. Kibler; discussed by M. R. Langham.

This is not a great book. It is a collection of well done conference papers. I believe graduate students, teachers, and researchers in agricultural marketing will find at least parts of the book useful, depending upon their interests. I am favorably disposed to printing conference papers which meet the quality standards represented in this collection.

JAMES D. SHAFFER
Michigan State University

Gray, James R., *Ranch Economics*, Ames, Iowa State University Press, 1968, viii + 522 pp. ($15.95)

"Way-of-life" ranching is being replaced by sophisticated computerized management of modern ranches. This transition requires that ranchers become more knowledgeable in economic theory. On the other hand, the author contends that economists generally lack knowledge of the pecularities of the ranching business. This book is designed to bridge the gap between ranchers and economists.

Chapters 1, 2, and 8 relate the development of ranching and briefly recount the political, social, physical, and economic circumstances that molded the ranch industry of the western United States. An elaborate discussion of resources and practices commonly found in six U.S. and four foreign production regions is given in Chapter 2. Gray failed to develop in any depth the competitive position of western producers except to note that costs of production were lower than those reported in Ohio and Indiana (Figure 4.4, page 112). Chapter 8 is perhaps the most interesting for those unfamiliar with management problems involving public and private land ownership. Attainment of adequate rangeland with a proper seasonal balance is concluded to be the major task facing ranchers. Differing goals held by ranchers and public agencies compound this problem. The always controversial grazing fee issue is discussed in this section. Material in Chapter 8 provides background information for much of the discussion about conservation in Chapter 10.

The remaining chapters are not dissimilar from what one finds in most farm management texts. Chapters 3, 4, and 5 discuss principles involved in firm decision making, record keeping, and analysis of financial and physical data.

The chapter on capital and credit is largely descriptive. Inadequate treatment is given to the future capital structure of ranches or the problem of redundant capital in the industry. Chapter 7 discusses the legal aspects of ranching and of necessity, it simply illustrates numerous areas of concern to ranchers.

A great deal of work has been done by economists on various range improvement practices. Chapter 11 contains voluminous results of these studies. It is concluded in this and in the final chapter that much more intensive use will be made of the range resource in the future.

The chapter on marketing describes the marketing process in general, with little depth in any area. The concluding chapter is a mixture of predictions by the author and others, along with techniques for individual ranch planning. A rather optimistic future for ranching is predicted based largely on increasing domestic population and incomes.

Dr. Gray has been closely associated with this subject for several years and has a thorough knowledge of the industry. The book is replete with results of studies done in the West. His familiarity with the complex subject may have led to the inclusion of so many subjects, few of which are treated in any depth. The book purports to be designed for ranchers and students. As with many attempts to satisfy two audiences, the results are not entirely satisfactory to either group. It seems that the treatment of economic theory is somewhat obscure for classroom use. The book contains over 500 pages; however, treatment of most issues is so cursory that ranchers will have to resort to other sources for further assistance.

Individuals interested in the livestock industry or the range resource will find selected portions of this book of interest. It also provides a rather good bibliography of research done on ranching in the West.

LEROY ROGERS
Washington State University

Myrdal, Gunnar, *Asian Drama, An Inquiry into the Poverty of Nations,* 3 vols., New York, Pantheon Books, 1968, xxix + 2284 pp. ($8.50 paper, $25 cloth.)

Anyone seriously interested in the development problems of South Asia should own a copy of, or have access to, this work. It is a vast repository of information concerning the political, sociological, and economic aspects of the development of South Asian countries. But it is not a work that anyone would *want* to read straight through anymore than one would want to read an encyclopedia straight through—and for the same reasons. Myrdal's *Asian Drama* is an encyclopedic work of development problems of South Asia. And, although I personally have a deep commitment to the development problems of that area, *Asian Drama* pressed more knowledge on me in one short period of time than I was seeking or could absorb.

Employing both an historical and an institutional approach, Gunnar Myrdal and a team of assistants have produced a great reference work on the development problems of South Asia. And it is in these terms that the work should be judged and used, although it is probable that Myrdal would not want his work, *Asian Drama,* judged in this manner. He argues in the Preface, ". . . what I have reached for in this book . . . is a tentative theory, one that coordinates in a systematic manner a general conception of what is happening in the region of South Asia. . . ." And in the Prologue Myrdal states, "The title of the book, *Asian Drama,* was chosen in order to express the conception of events in South Asia held by the author at the beginning of his work and fortified in the course of study. Behind all the complexities we sense a rather clear-cut set of conflicts and a *common theme* as in a drama [italics mine]. The action in this drama is speeding toward a climax. . . ." So Myrdal feels that a general theory, or a theme, or an approach, binds together in a unified whole the many facets of this huge work on South Asia. Perhaps. But this reviewer did not find the unifying theme. For him it remains an important reference work on the political, social and economic conditions of South Asia in a developmental setting.

In the sense of a reference work, Myrdal and his assistants describe in detail the political history of the region, including the partition of Imperial India and other border disputes; the economic realities of the region, including detailed discussions of population and resources, national output, and structure of the economy, levels of living, and foreign trade; problems of labor utilization in agriculture and industry; agricultural policy; population policy; and problems of population quality, including health, education, and school systems. The discussion of each of these subject areas usually is developed in depth with respect to India, and somewhat more superficially for the other countries of the region.

This reviewer found "Part Four: A Third World of Planning" the most instructive and most important section of the book. In this section, Myrdal deals with the spread of the ideology of planning; the paradox of egalitarian objectives and social and income inequality; the dilemma of the "soft state," which seeks reform but requires little of its citizens; the cumulative tendency toward excessive and discretionary controls over the private sector; and the causes and effects of corruption. For the person concerned with economic development but unfamiliar with social and political conditions in South Asia, this section must be highly revealing; for the person who has worked in South Asia (as the reviewer has), this section helps one to understand the quagmire from which he could never quite extricate himself. In this sense, this section is instructive.

But the ideas developed in this section have a greater importance—a greater relevance. Myrdal tells the political and intellectual leaders of South Asia some hard truths about themselves, which they must come to appreciate and to act upon, if they are ever to achieve the rates of economic growth to which they aspire. Myrdal states boldly, for example . . . "there is little hope in South Asia for rapid development without greater social discipline. . . ." This is strong medicine, but from the liberal, Myrdal, the political leaders and intellectual elite are swallowing hard and taking it (certainly no American could discuss the "soft state" and government corruption the way Myrdal has, and still find acceptance in India). But reviews of *Asian Drama* in Indian Newspapers and Journals in late spring of 1968 suggest that the message in this part of the book is being discussed with reasonable calm and accepted to some degree, regardless of the hurt to national pride.

Myrdal devotes two chapters to agriculture. The first entitled "Labor Utilization in Traditional Agriculture" delves deeply in the structure of rural society, including village life, and rates and forms of labor utilization under varying institutional arrangements. This is an excellent chapter, providing a careful description of working conditions and arrangements in rural areas—primarily in rural India. The second chapter entitled "Agricultural Policy" deals with the need to increase food production and takes up the technical possibilities and the institutional restraints. But he misses completely the important technological developments that have occurred in the agriculture of South Asia in the past few years. In part, this is due to the cut-off date of the book, July 1967. But more important, it is due to Myrdal's preoccupation with institutional developments. He argues in this chapter that:

> The major theme of our analysis will be that the success of technological reforms, designed primarily to increase the cultivated acreage and raise agricultural yields through variations in techniques and the input of capital, hinges largely on the extent of prior, or at least simultaneous, institutional changes.

Concentrating on institutional changes, Myrdal has missed completely the technological revolution that is now occurring in food grain production in South Asia. Like another great master, Malthus, Myrdal has failed to observe the technological dynamics of agriculture at a time of very great importance, through his preoccupation with other matters—in this case institutional changes in agriculture.

When one has finished reading chapter 33, the final chapter of *Asian Drama* (on page 1,828), he has not finished the work. There remain 378 additional pages of appendices. This reviewer did not read all of these appendices, but he did read appendix 2, "The Mechanism of Underdevelopment and Development and a Sketch of an Elementary Theory of Planning for Development," and as in Marshall's Principles, some of the most illuminating material in the book is to be found in the appendices. Appendix 2 is a must reading for anyone concerned with "The Theory of Planning for Development," and probably will become as well known and as well used as appendices 1 and 2 dealing with "Valuations" in *An American Dilemma.*

Again let me repeat that *Asian Drama* is a work that anyone specializing in development problems, or South Asia, will want to own. It is a great reference work, which probes in depth many, many political, social, and economic problems of South Asia. But it is not the kind of a work that one reads straight through either for pleasure or in pursuit of a logical theory or a general conceptual picture. *Asian Drama* comes close to duplicating South Asia itself for variation, complexity, and size.

WILLARD W. COCHRANE
University of Minnesota

Weymar, F. Helmut, *The Dynamics of the World Cocoa Market,* Cambridge, The M. I. T. Press, 1968, ix + 253 pp. ($15.00)

This research monograph is likely to be of value to traders, students of price theory, and econometricians. For traders, it describes the cocoa market for the 1953–63 period. Students of futures markets will find a revision of the "supply of storage theory" explaining monthly price movements. Econometricians will want to evaluate the transition from theory to empirical measurements, the use of *a priori* information, and the unusually varied series of tests applied to the results.

Inevitably, the study begins with a description of the world cocoa market. It identifies the major fluctuations of the market due to changes in consumption (as when Britain ended war controls) and in production (as when Brazil attempted to improve prices by withholding supply in 1957–58). It also describes the procedures actually used by traders to forecast the size of the annual crop, because forecasts play an essential role in the behavior of commodity prices. This description is supplemented by a month by month analysis of the market over ten years. The 120 paragraphs are kept in an appendix for the benefit of the cocoa trader or the dedicated reader.

No attempt is made to analyze the long-run response to price. This is a perfectly legitimate decision because a cocoa tree can be kept in production for more than forty years. The study deals with a price-consumption sub-system which must explain the nature of the relationships and adjustment lags between prices, inventories, expectations regarding inventories, consumption, and consumption expectations, as they respond to variations in world cocoa production. These five endogeneous variables do not appear explicitly in the final derived sub-system which includes only a spot price equation, a consumption equation, and a consumption-expectations equation. These equations are estimated separately.

The spot price equation is the most important of the three. It is based on a revised form of the "supply of storage theory" which was previously published by the author in the *American Economic Review* of December 1966. This theory says that "the spread between the spot price and expected spot price and/or the futures price relating to some relatively distant horizon time is a function of expected inventory behavior over the horizon interval" [p. 51]. Working's earlier conclusion is that intertemporal price spreads are "in general determined by the existing inventory level alone and not by events expected in the future" [p. 57]. This apparent contradiction vanishes when the author shows that Working's conclusion is applicable to observations over shorter time periods, like three months. The result is a welcome clarification. The theory is well presented and provides a useful reference for further discussion.

The conclusion of the theory is that the spot price can be approximately stated as a function of the current inventory ratio, the forecasted inventory ratio for some finite horizon, and the expected long-run equilibrium levels of price and inventory ratio. One month is used as the time unit for the estimation. When such information is not available, appropriate time series are constructed. The final form of the spot price function is reached through a series of intermediate regressions and equation substitutions. This weakens the value of the results for a test of the revised supply of storage theory. Moreover, it seems that at one step the author has overlooked an identification problem. In the elimination of the first term of equation number 4.23 [p. 71], the use of long-run equilibrium conditions forces a specific value on $ln\overline{V}^{*}s$, the logarithm of the expected end-of-year inventory ratio. This value differs from the results on page 76.

Once the spot price function has been estimated, it is subjected to several tests. It is found that a trend equivalent to the trend in cocoa production should be added to the long-run equilibrium price level. The parameter estimates have plausible values, although some are very close to the lower bounds of the previously established *a priori* range for the estimates. An F-test applied to two sets of estimates obtained by dividing the sample into two periods shows that, despite a good fit, the estimated structure is not stable. The results over the entire period explain 94 percent of the variance of the monthly average cocoa price. To eliminate the influence of serial correlation, which is inevitable when working with monthly data, the definitive spot price equation is estimated by generalized least-squares.

Of the two remaining equations of the system, the consumption equation is estimated in two ways. A first form is estimated indirectly on a quarterly basis using several forms of lagged responses to price changes. It fails to account for the impact of income, a time trend and the impact of the price of sugar, and it is replaced by another form based on direct estimation. Finally, there is an equation representing consumption expectations. In estimating these equations, as in the rest of the study, the author displays skills and cleverness in using the data, especially when he uses *a priori* information to handle expectations. The statistical results are again quite good.

Once the entire price-consumption subsystem has been estimated, its dynamic properties are tested in several ways. First, a test of the impact of actual exogenous variables on the system shows that endogenous variables are well predicted. A further test provided by the comparison of the cross-variance function between the exogenous producer sales and the endogenous consumption rate for actual and simulated variables is also satisfactory. But, why not test price movements as well? Finally, the author investigates the resonance properties of the system. Starting with a set of well-defined initial conditions, he studies how the system filters a periodic disturbance added to steady-state variables. This procedure allows him to investigate reactions to stochastic as well as deterministic variations. A "gain function" between price and consumption tends to show that the sub-system filters out very short periods and favors periods over nine years of length. An estimation of the response to a 20 percent crop failure confirms this sensitivity to a nine-year period. Does this have empirical implications for the stabilization of the market?

This is a good study. It achieves its purpose of describing the essential features of the world cocoa market. It avoids a common weakness of other studies in its effort to develop an appropriate theory before making empirical measurements. The author displays remarkable skills in handling the data and in making use of all the information available; his introduction of a variable time span in the estimated spot price function is very interesting. However, he cannot extricate himself from the dilemma of choosing between generating data to fit an acceptable theory and adjusting the theory to fit the existing information. He personally favors the first alternative. As time passes, it will take more and more of this kind of effort to dispel the current uneasiness about econometric studies which stand halfway between economic theory and reality. We have here a serious reference work for economists and econometricians studying the behavior of soybeans, coffee, sugar, and other commodity prices.

BERTRAND RENAUD
University of Hawaii

Yotopouolos, Pan A., ed., *Economic Analysis and Economic Policy*, Training Seminar Series 6, Athens, Center of Planning and Economic Research, 1966, 205 pp. (Price unknown)

This book consists of six chapters written by six different authors. The subject matter of the book deals with economic planning, particularly investment analysis. It does not cover the broad spectrum of economic analysis and policy, as the title of the book may imply. Within this subject matter, the central theme of the book is, in the editor's words, "to circumstantiate the nature of the contribution that the economist can make in the shaping of policy recommendations." The book turns out to be primarily about the applications of cost-benefit analyses to actual projects.

The first four chapters go together quite well and are not difficult reading. The beginning graduate student should have little trouble with these. However, there is little in these that will interest the economist specializing in investment analysis. The last two chapters, and particularly the last one, will appeal only to the specialist. It is even difficult for anyone but the specialist to see the logical tie-in of these chapters with the rest of the book.

The first chapter, by Goldberger, stresses the need for interplay between the economist and the policymaker. It is assumed that the policymaker is the best qualified to specify the welfare function for society and he should do so. Goldberger ignores the problems and controversies surrounding this assumption. The economist's role is to call to the attention of the policymaker variables that must be changed to meet the desired levels of the goals. If some of these variables have values attached, then the policymaker must decide the levels of all variables having values. The economist specifies the relationships among the variables.

The second chapter, written by Tillo Kuhn, sketches an overall framework for investment analysis. Subsequent chapters fit into this framework, but they elaborate only on a few of the topics sketched. The framework deals with the applied problems of investment analysis, such as defining the analytical boundaries and goals of the problem, getting an inventory of means and environmental factors, and choosing the best tools to make the choice among various means. The chapter also includes the results of analyzing a number of past research projects and shows some startling weaknesses in these projects. The main lesson of this chapter is the discrepancy that exists between what can be done with existing tools and what actually has been done.

The third chapter, by Berney, shows that factors other than profits should be taken into consideration in investment analysis. He emphasizes the alternative uses of scarce government funds and the level of employment. He also outlines a scheme for establishing discount rates by constructing a demand schedule for investment funds.

The fourth chapter, by Kyrtsis, is a hypothetical example of an investment that is unprofitable for private enterprise but profitable for the government. The difference lies in the prices relevant to each group.

Readers of this journal will find the fifth chapter familiar, as a shorter version of it was published in the May 1967 issue [p. 476]. The basic argument of this chapter is that the irregularity of service flows from stocks leads to a bias in production function coefficients when the stocks themselves are used. Methods for estimating service flows are presented. An empirical example shows that the flow concept does a better job of estimating coefficients than does the use of capital stock.

The final chapter concerns efficient paths of capital accumulation and is a subset of the literature that has evolved from the basic framework of Chapter 12 of Dorfman, Samuelson, and Solow. This chapter shows that the proportion of the first period envelope that will lead to the efficient envelopes in subsequent periods is very small. This implies that there is a need for long-range planning, since it is doubtful if the invisible hand will be able to keep the capital allotted to the production of different goods in the optimal proportions.

The book presents some important concepts in the area of applied investment analysis. These ideas are highlighted with actual or hypothetical empirical examples. Many of the concepts are not original and many are more fully explicated elsewhere. The book has to be faulted for weak continuity from chapter to chapter. The book is not a comprehensive treatment of the subject matter. It develops some topics and merely mentions others.

DAVID W. PRICE
Washington State University

Books for listing in this section should be sent to the Book Review Editor (see inside front cover for address).

Books Received

Aid to Agriculture in Developing Countries, Paris, Organization for Economic Cooperation and Development, 1968, 186 pp. $5.00 paper.

Andreano, Ralph L., Evan Ira Farber, and Sabron Reynolds, *The Student Economist's Handbook, A Guide to Sources,* Cambridge, Massachusetts, Schenkman Publishing Company, 1967, x + 159 pp. $1.50 paper.

Announcements

1969 AAEA ANNUAL MEETING

The 1969 Annual Meeting of the AAEA will be held on August 17–20 at the University of Kentucky, Lexington, Kentucky.

Dr. Robert W. Rudd is Chairman of the Department of Agricultural Economics and Dr. John C. Redman is in charge of local arrangements. Suggestions or requests, including needs for space for committee sessions to be held before or after the meeting, should be addressed to Dr. Redman.

Suggestions for the program should be sent to President Harold F. Breimyer, Department of Agricultural Economics, University of Missouri, Columbia, Missouri 65201.

CONTRIBUTED PAPERS—1969 AAEA ANNUAL MEETING

Contributed papers in any area of agricultural economics are solicited. Priority in selection will be given to papers that identify new or neglected problems, or that demonstrate or propose new approaches, new concepts or improved methods applicable to recognized problems. Contributions treating collegiate and adult teaching as well as research are encouraged.

At least four sectional meetings are planned for contributed papers with a maximum of four papers in each session. The specific subject matter groupings for each session will be determined by the papers submitted.

Rules for Submitting Contributed Papers

1. The maximum length of any contributed paper shall be seven double-spaced typed pages including text and all other material such as footnotes, tables, and charts. Place all references, alphabetized by author, in a numbered list at the end of the paper in a section titled "References." When you refer in the text to a publication on this list, insert its number in brackets, including specific page number if necessary. Example: [7, p. 643]. See "Guide for Submitting Manuscripts" on the inside of the back cover of the *American Journal of Agricultural Economics.*

2. Five copies of the paper and a one-page abstract are to be submitted to the general chairman before May 1, 1969. The general chairman will group the papers and forward them to section chairmen, notifying each author of the group to which his paper was assigned. The abstract will be used as a guide for grouping the papers.

3. It shall be the responsibility of each section chairman in consultation with several of his departmental colleagues to select four papers for presentation at the annual meeting.

4. It is recommended that 50 copies of the contributed papers be brought to the annual meeting by the author for distribution.

The following committee is in charge of the program: Milton Manuel, Kansas State University, general chairman; Sharon Hoobler, U. S. Department of Agriculture, Washington, D.C.; Raymond Leuthold, University of Illinois; Chester McCorkle, University of California, Davis; Travis Manning, University of Alberta; and Andrew Vanvig, University of Wyoming.

Requests for further details should be directed to the general chairman, Milton Manuel.

UNDERGRADUATE DEBATE, PUBLIC SPEAKING, AND ESSAY COMPETITIONS

Competition is open to any undergraduate student interested in agricultural economics. Participants are encouraged to become members of chartered student-section affiliates of the American Agricultural Economics Association but such membership is not required to enter the various contests. No individual student may enter both the debate and the public speaking competitions in the same year.

Public Speaking Competition

The public speaking may be on any topic in the area of agricultural economics. Each speech will be limited to 10 minutes' duration.

Chartered chapters or individuals must declare their intention of participating in the public speaking competition by writing not later than June 1, 1969, to Kenneth B. Boggs, Chairman, AAEA Student Activities Committee, Department of Agricultural Economics, University of Missouri, Columbia, Missouri 65201.

Debate Competition

The topic to be debated in 1969 is

Resolved: That federal legislation should be enacted to retard nonfarm corporate firms from either the operation or ownership of farms.

A declaration of intention to participate in the debate competition must be made in writing not later than June 1, 1969, to Kenneth B. Boggs, at the address given above. Names of contestants and/or alternates and coaches, along with the mailing address of each, should be included. Not more than one debate team from one school may participate in the debate contest.

Student Essay Contest

The essay contest does not require attendance at our annual summer meeting. It was developed primarily to provide an opportunity to participate for students who find it impossible to attend the annual meetings and for students whose abilities and interest tend to be in research and/or writing. The development and preparation of a manuscript for purposes of publication is one of the objectives of this contest. Essays may deal with any topic in agricultural economics, agricultural industries, or rural sociology. The 1969 award paper will be published in the 1969 Proceedings issue.

Manuscripts should not exceed 2,500 words in length and should be prepared according to instructions appearing on the inside of the back cover of the *American Journal of Agricultural Economics.* Manuscripts must be submitted in triplicate by July 1, 1969, to Robert Taylor, Department of Agricultural Economics, Purdue University, Lafayette, Indiana 47907.

AAEA DUES

Dues for 1969 are payable. The dues rates are as follows:

Regular membership	$10.00
Junior membership (graduate students, 3-year maximum)	5.00

Please mail your check, payable to the American Agricultural Economics Association or AAEA, to C. D. Kearl, Secretary-Treasurer, AAEA, Department of Agricultural Economics, Cornell University, Ithaca, New York 14850.

(The Executive Board of AAEA has discontinued joint memberships with other associations; in succeeding issues, we will provide information concerning membership requirements of other associations.)

BACK ISSUES NEEDED

The Secretary-Treasurer of the AAEA is authorized to pay $1.00 each for any of the issues of the JFE listed below.

Year	*Volume*	*Issues*	*Year*	*Volume*	*Issues*
1919	1	1, 2, 3	1951	33	1, 2, 3
1920	2	1, 2, 2, 4	1952	34	5
1921	3	1, 2, 3, 4	1953	35	1, 5
1922	4	1, 2, 3, 4	1954	36	2
1923	5	1, 2, 4	1955	37	1, 2, 3, 4, 5

1947	29	1, 2, 4–1	1966	48	3–1
1948	30	1	1967	49	1–1, 1–2

JOURNALS should be mailed to C. D. Kearl, AAEA, Dept. of Agricultural Economics, 455 Warren Hall, Cornell University, Ithaca, New York 14850.

News Notes

UNIVERSITY OF ARIZONA

Appointment: **Resat Aktan**, University of Ankara, Turkey, visiting professor, 1968–69.

Leaves: **Robert S. Firch** (AJAE Editorial Council), sabbatical, Stanford, Fall 1968; **Robert A. Young**, Resources for the Future, Washington, D.C., 1968–69.

UNIVERSITY OF ARKANSAS

Appointments: **J. Martin Redfern**, assistant professor, resource economics; **Ralph Gene Martin**, M.S. Arkansas, 1968, and **Clyde Stuart, Jr.**, M.S. Arkansas, 1968, instructors.

UNIVERSITY OF CHICAGO

Appointments: **Hans Joachim Bodenhoefer**, Technische Universitat, Berlin, and **Franciszek W. Budzynski**, Warsaw Agricultural University, Ford Foundation Post-Doctoral Fellows; **D. P. Chaudhri**, Delhi University, Rockefeller Foundation Post-Doctoral Fellow; **Steven C. Cheung**, assistant professor; **Barry R. Chiswick**, University of California, Los Angeles, visiting professor; **Joseph L. Havlicek**, Purdue University, Faculty Fellow; **Tara Shukla**, University of Bombay, Post-Doctoral Fellow of Agricultural Development Council and Department of Economics.

Awards: **Theodore W. Schultz**, Doctor of Laws, University of Illinois and University of Wisconsin, 1968.

COLORADO STATE UNIVERSITY

Appointments: **Edward K. Smith**, formerly deputy assistant secretary of Commerce, chairman, department of economics. Additional appointments in economics: **Richard C. Barth**, **Huntley H. Biggs**, **Terutomo Ozawa**, assistant professors; **Rodney D. Peterson**, **Liang-Shing Fan**, associate professors; **Robert L. Darcy**, **Richard G. Walsh**, professors; **Donald M. Sorenson**, extension assistant professor; **Robert E. Whedbee**, faculty affiliate.

Leave: **Loyal M. Hartman**, sabbatical, Harvard.

CORNELL UNIVERSITY

Leaves: **Solon L. Barraclough**, returned from extended leave at the Chilean Agrarian Reform Training and Research Institute, Santiago; **David L. Call**, sabbatical, Massachusetts Institute of Technology; **William G. Tomek**, sabbatical, Food Research Institute, Stanford.

AWARDS: **Glenn W. Hedlund**, annual Agricultural Counselor Award, Farm Credit Banks of Springfield, Massachusetts; **Clifton W. Loomis**, annual Epsilon Sigma Phi Achievement Award for excellence in extension work; **E. A. Lutz**, Fullbright Award at Royal College of Agriculture, Norway.

DUNLAP and ASSOCIATES, INC.—AGRI RESEARCH DIVISION (Manhattan, Kansas)

APPOINTMENTS: **James K. Allwood**, M.S. New Mexico State, 1968; **Larry Bedford**, M.S. Missouri, 1968; **Gary Mennem**, M.S. Oklahoma State, 1968; **Burton Tribble**, M.S. candidate, Kansas State; **Barry Rhine**, graduate student, Kansas State.

ECONOMIC RESEARCH SERVICE, USDA

(EDD is Economic Development Division; ESAD is Economic and Statistical Analysis Division; FAS is Foreign Agricultural Service; FDTD is Foreign Development and Trade Division; FPED is Farm Production Economics Division; FRAD is Foreign Regional Analysis Division; MED is Marketing Economics Division; NRED is Natural Resource Economics Division; PASA is Participating Agency Service Agreement; SRS is Statistical Reporting Service.)

APPOINTMENTS: **Walter Armbruster**, MED, at Corvallis; **Sanford Belden**, MED, at Purdue; **Larry M. Boone**, formerly University of Tennessee, 2-year assignment in Colombia on USAID/PASA team; **Walter E. Epps**, formerly Battelle Memorial Institute, MED; **Russell L. Gum**, FPED, at Tucson; **Blake Imel**, MED, at Berkeley; **Edward Jesse**, MED, at Madison (NCM-44 Regional Project); **Richard Johnson**, NRED, at East Lansing; **Philip L. Mackie**, Ph.D. Maryland, 1968, FAS at Washington, D.C.; **Masao Matsumoto**, MED, at Berkeley; **Willis Middlemiss**, NRED, at Corvallis; **Malek M. Mohtodi**, formerly Utah State University, FRAD; **Terry L. Roe**, Ph.D. candidate, Purdue, MED, at St. Paul; **J. Newell Sorenson**, NRED, at Bismarck; **Bruce H. Wright**, MED.

TRANSFERS: **Fred H. Abel**, from FPED to EDD; **John H. Berry**, FPED, from Lafayette to Urbana; **John Braden**, NRED, from Little Rock to Alexandria, Louisiana; **Lee Christiansen**, NRED, from Lincoln to East Lansing; **Richard Cowled**, from NRED to Forest Service; **Arthur Daugherty**, NRED, from Washington, D.C. to University Park, Pennsylvania; **Merlin Erickson**, NRED, from Temple, Texas, to Lincoln; **Henry C. Gilliam, Jr.**, FPED, from Clemson to Raleigh; **Wade F. Gregory**, FDTD, to USAID/PASA, Colombia (2 years); **Jerald Gunnelson**, MED, from Lafayette to Madison; **Richard Hall**, MED, from 2-year assignment in Bolivia; **Hugh A. Johnson**, NRED, from Temple, Texas, to Jackson, Mississippi; **Ray Lanier**, NRED, from East Lansing to Berkeley (to be leader of new Southwest Resources Group); **Dallas Lea**, NRED, from Morgantown to Washington, D.C.; **Percy Luney**, NRED, to 1-year assignment as staff assistant to ERS Administrator; **Donavon D. MacPherson**, USAID/PASA, from Ecuador to Paraguay (2 years); **Nathan Mallett**, NRED, from Ann Arbor to Washington, D.C.; **Neil R. Martin, Jr.**, FPED, from Athens, Georgia to Urbana; **Howard A. Osborn**, USAID/PASA in Bolivia to FAO in Mexico (2 years, on world census of agriculture); **James Schwinden**, USAID/PASA, from El Salvador to Colombia; **Bobby H. Robinson**, FPED, from Clemson to Washington, D.C.; **W. Neil Schaller** (AJAE Editorial Council), from

FPED to International Agricultural Development Service, USDA, Washington, D.C.

LEAVES: **Wendell Clement**, MED, to Federal City College (new Land Grant College in Washington, D.C.), 1 year, to develop marketing program; **Allen B. Paul** (AJAE Book Review Editor), MED, to University of Hawaii, 1968–69.

RESIGNATIONS: **Alvin C. Egbert**, to International Bank of Reconstruction and Development; **Ivan Hanson**, NRED, to Planning Research Corporation, Washington, D.C.; **Frederick J. Rafeld**, FPED, to Louisiana State University; **Paul E. Tix**, FPED, to St. John's University.

AWARDS: **Gene Harris**, NRED, Little Rock, National Institute of Public Affairs 1-year career training award, Stanford University; **Adrian Haught**, NRED, Upper Darby, National Institute of Public Affairs 1-year training award, University of California, Irvine.

EXTRAORDINARY: **Wells Hutchins**, 80, celebrated his 60th anniversary as a USDA employee on July 27, 1968. Since his retirement in 1958, he has been reemployed each year in the Natural Resource Economics Division to complete his multi-volume work on the water laws in western states.

UNIVERSITY OF FLORIDA

APPOINTMENTS: **Wallace K. Boutwell**, Ph.D. North Carolina State, 1968, **J. Kamal Dow**, formerly with Deere & Company, **Fred H. Tyner**, formerly of Louisiana State, associate agricultural economists

AWARDS: **Max R. Langham**, 9-month Faculty Development Grant, University of Minnesota; **Stanley E. Rosenberger**, 9-month Faculty Development Grant, Purdue University.

UNIVERSITY OF GEORGIA

APPOINTMENTS: **David E. Weisenborn**, Ph.D. Florida, 1968; **Floyd W. Williams**, associate professor; **L. Harlan Davis**, formerly with Agency for International Development, Bogota, Colombia, and **John W. Nixon**, Ph.D. candidate, Michigan State, assistant professors.

UNIVERSITY OF ILLINOIS

APPOINTMENTS: **W. D. Buddemeister**, formerly of USAID, Jawaharlal Nehru Agricultural University, India, associate head of department and assistant director, International Programs of College of Agriculture; **Melvin Wagner**, formerly of the Agricultural Development Council, Kasetsart University, Thailand, and **Harold D. Guither**, associate professors; **Alfred G. Harms**, associate professor, assigned to Uttar Pradesh Agricultural University, India; **Takashi Takayama**, formerly with University of New England, N.S.W., Australia, joint professorship in economics and agricultural economics; **Ian Marceau**, Ph.D. Illinois, 1968, assistant professor of computer science; **Howard R. Peverly**, M.S. Illinois, 1968, fieldman, Illinois farm business farm management service, Morrison; **Willitt Pierce**, M.S. Illinois, 1968, statistical service unit; **Erman E. Schairer**, M.S. Illinois, 1968, fieldman, Illinois farm business farm management service, Bloomington.

LEAVES: **Robert P. Bentz**, assistant to vice president, University of Illinois, until July 1, 1970; **J. M. Holcomb**, Ford Foundation, Intensive Agricultural

Development Program, New Delhi, India; **Stephen C. Schmidt**, sabbatical, University of Manitoba; **Robert B. Schwart**, 2-year appointment at Uttar Pradesh Agricultural University, India.

RESIGNATION: **Roger J. Vandenborre**, to Docent (associate professor), Department of Applied Economics, University of Louvain, Belgium.

IOWA STATE UNIVERSITY

APPOINTMENTS: **Ivo Cupic**, Economic Advisor to Economic Chamber of Bosnia and Herzegovina, Sarajevo, Yugoslavia, visiting professor; **Jordan Krsteski**, Faculty of Agriculture and Forestry, Skopje, Yugoslavia, and University Institute of Economics, visiting professor; **Augustyn Wos**, University of Maria Currie-Sklodowska, visiting lecturer.

UNIVERSITY OF MAINE

APPOINTMENTS: **Reginald K. Harlan**, formerly with University of Wyoming Afghanistan Project, associate professor; **S. E. Shehata**, University of Ain Shams, Cairo, Egypt, visiting professor, 1968–69.

LEAVE: **Wallace C. Dunham**, sabbatical, Cornell University (studying for Ph.D.)

UNIVERSITY OF MASSACHUSETTS

APPOINTMENTS: **John Foster**, Director, Center for International Agricultural Studies; **N. Eugene Engel**, acting department head, in absence of **J. B. Wyckoff**, on leave until July 1, 1969; **Robert Christensen**, associate professor; **Robert Forste**, instructor.

MICHIGAN STATE UNIVERSITY

APPOINTMENT: **David Armstrong, associate professor.**

LEAVES: **A. Allan Schmid**, Systems Analysis Group, Washington, D.C.

UNIVERSITY OF MINNESOTA

APPOINTMENTS: **Martin E. Abel**, formerly Deputy Assistant Secretary for International Affairs, Office of the Secretary, USDA, professor; **Willis E. Anthony**, assistant professor and extension economist; **Buddy G. Crewdson**, formerly of Upper Midwest Research Development Council, assistant professor and extension specialist in resource development; **Mathew D. Shane**, Ph.D. candidate, Purdue, assistant professor.

LEAVES: **Robert E. Evenson**, visiting professor, Southern Methodist University, Dallas, 8 months; **James P. Houck, Jr.**, Agricultural and Technical State University, Greensboro, North Carolina, 1969 spring quarter.

UNIVERSITY OF MISSOURI

APPOINTMENTS: **Kenneth C. Schneeberger**, Ph.D., Oklahoma State, 1968, assistant professor; **Roger Halstead**, M.S. Missouri, 1968, farm management agent.

LEAVES: **Charles L. Cramer**, Harvard (6 months); **Dale K. Colyer**, Fullbright lecturer, Argentina, July-November 1968.

MONTANA STATE UNIVERSITY

APPOINTMENTS: **Richard J. McConnen**, department head, replacing **Clarence Jensen**, resigned to resume as professor; **Oscar R. Burt**, formerly at Missouri, professor; **Martin S. Stauber**, Ph.D. Missouri, 1968, and **Michael D. Copeland**, Ph.D. candidate, Colorado, assistant professors.

LEAVES: **Edward H. Ward**, 2-year assignment, Agricultural Development Council, Boger, Indonesia; **Merle Quenemoen**, returned as extension economist after completing 2-year assignment with Oklahoma State University program at Haile Selassie I University, Ethiopia.

AWARD: **Gail Cramer**, Ph.D. Oregon State, 1968, Edwin G. Nourse Award for outstanding Ph.D. thesis, 1968.

NEW MEXICO STATE UNIVERSITY

APPOINTMENTS: **Frank Osterhoudt**, Ph.D. Wisconsin, 1968, and **James Taylor**, Ph.D. Wisconsin, 1968, assistant professors.

OKLAHOMA STATE UNIVERSITY

APPOINTMENTS: **Leo V. Blakley**, acting department head, in absence of **James S. Plaxico**, on leave to Ford Foundation, Bogota, Colombia; **Odell L. Walker**, assistant dean of Graduate College, OSU, ½ time; **Darrel D. Kletke**, Ph.D. OSU, 1968, and **Dean F. Schreiner**, assistant professors.

LEAVE: **Leonard F. Miller**, sabbatical in United States, after 7-year assignment in Ethiopia.

PURDUE UNIVERSITY

APPOINTMENTS: **Gordon D. Honegger**, 2-year post-doctoral assignment for systems analysis in the swine industry; **Josef L. Hesselbach**, Universität Hohenheim, West Germany, visiting professor, one year; **Bertil Johnsson**, Head, Division for Applied Research in Production Economics, Uppsala, Sweden, visiting professor, 1968–69; **Klaus Riebe**, University of Kiel, Germany, visiting professor, September 1968 through March 1969; **Stanley E. Rosenberger**, University of Florida, visiting professor, 1968–69.

AWARDS: **Harry W. Leonard**, honorary American Farmer Degree by the National Future Farmer of America; **Henry A. Wadsworth**, Outstanding Service Award by Purdue Extension Specialists Association.

TEXAS A&M UNIVERSITY

APPOINTMENTS: **John P. Nichols**, Ph.D. Cornell, 1968, **Thomas L. Sporleder**, Ph.D. Ohio State, 1968, **Robert R. Wilson**, Ph.D. candidate, Minnesota, assistant professors; **Chancey C. Connolly, Jr.**, Ph.D. Ohio State, 1968, associate professor at Lower Rio Grande Valley Research and Extension Center, Weslaco, Texas; **Jim McGrann**, M.S. Washington State, 1968, Agricultural Advisor, Texas A&M University/AID Project, Argentina; **John J. Siebert**, extension economist in grain marketing; **John Steele**, Ph.D. Wisconsin, 1968, assistant professor, Argentina research team.

UTAH STATE UNIVERSITY

APPOINTMENT: **Marcelo Peinado**, Ph.D. Wisconsin, 1968, to staff, University's OAS contract in Latin America.

LEAVE: **D. Delworth Gardner**, Resources for the Future, Washington, D.C. one year.

UNIVERSITY OF WISCONSIN

APPOINTMENTS: **Benjamin Villanueva**, Ph.D. Wisconsin, 1968, assistant professor, Land Tenure Center.

LEAVES: **Marvin Miracle**, International Development Research Center, Indiana University, one year; **Kenneth Parsons**, 2-year assignment, University of Wisconsin-AID project in Ibadan, West Nigeria; **John Strasma**, returned as professor after 2½ years as director of Land Tenure Center program and professor in Graduate Economics faculty of University of Chile; **William C. Thiesenhusen**, sabbatical, Harvard.

OTHER APPOINTMENTS

Armed Al-Araji, Ph.D. Missouri, assistant professor, University of Idaho.

Dale O. Anderson, Director, Water Institute, North Dakota State University, replacing **Thor A. Hertsgaard**, resigned to resume as associate professor, NDSU.

A. Wayne Bartholomew, Ph.D. Cornell, 1968, to faculty, Benedict College, South Carolina.

John D. Bates, Ph.D. Maryland, 1968, Marketing Research Division, Giegy Agricultural Chemicals, Ardsley, New York.

Ujagar S. Bawa, Ph.D. Cornell, 1968, to faculty, Wilkes College, Wilkesbarre, Pennsylvania.

Turgut Bayyurt, M.S. Maryland, 1968, Ministry of Planning, Government of Turkey.

Blaine W. Bickel, M.S. Wyoming, 1968, Federal Reserve Bank, Kansas City.

Fred Bordeaux, Ph.D. Michigan, 1968, assistant professor, University of Kentucky.

Theodore Cook, Ph.D. Wisconsin, 1968, International Development Foundation, Santiago, Chile.

Charles M. Cuskaden, Ph.D. candidate, Michigan State, assistant professor, The University of Tennessee.

Stanley G. Detering, Ph.D. candidate, University of California, Davis, lecturer in resource economics.

James L. Driscoll, Ph.D. Oklahoma State, 1968, National Program in Agricultural Marketing, MASUA, Colombia.

Ismail El-Zabri, Ph.D. Illinois, 1968, Near East Branch, FAO, Rome.

Douglas Erikson, Ph.D. Missouri, 1968, assistant professor, Central Missouri State College, Warrensburg.

Raymond Folwell, Ph.D. Missouri, 1968, assistant professor, Washington State University.

Allan R. Frampton, Ph.D. Cornell, 1968, Massey University, New Zealand.

Jerry E. Fruin, Ph.D. candidate, UC, Berkeley, and formerly with General Mills, manager of operations research, finance division, Hamm Brewing Co.

Aklu Girgre, M.S. Maryland, 1968, Ministry of Agriculture, Ethiopia.

Edward Jansen, resource economics faculty, University of New Hampshire.

Ray M. Johns, Ph.D. candidate, Maryland, and formerly with ERS, director of economic development, Calvert County, Maryland.

Paul H. Kipps, Ph.D., Cornell, 1963, to faculty, Madison College, Harrisonburg, Virginia.

Precioso C. Kuhonta, Ph.D. Illinois, 1968, Forest Economics Research Institute, Department of Forestry and Rural Development, Ottawa, Canada.

T. G. Kwon, M.S. Illinois, 1968, Office of Rural Development, Korea.

Teng-Hui Lee, Ph.D. Cornell, 1968, Joint Commission on Rural Reconstruction, Taiwan.

J. Rodney Lemon, Ph.D. Illinois, 1968, assistant professor of economics, Wisconsin State University, Platteville.

Simon Y. LeNaelov, Ph.D. Cornell, 1968, Department of Agriculture, Quebec, Canada.

Joseph V. Leunis, Ph.D. Illinois, 1968, Belgium Boerenbond, Brussels.

Sergio Maturana, Ph.D. Wisconsin, 1968, graduate faculty of economics, University of Chile, Santiago.

Jerry D. Michel, M.S. Wyoming, 1968, Metropolitan Life Insurance Company, Fresno, California.

Vincent R. McDonald, Ph.D. Maryland, 1968, assistant professor of economics, Howard University, Washington, D.C.

William R. Morrow, Ph.D. Tennessee, 1968, assistant professor, Eastern Kentucky State College, Richmond, Kentucky.

Donald Muir, Ph.D. Illinois, 1968, Forest Economic Research Institute, Government of Canada, Ottawa.

Tridib Mukherjee, Ph.D. Maryland, 1968, assistant professor, Fairmont State College, West Virginia.

A. Gene Nelson, Ph.D. candidate, Purdue, assistant professor, Oregon State University.

Ray P. Nightingale, Ph.D. Cornell, 1968, to faculty, American University, Beirut, Lebanon.

David W. Norman, assistant professor, Kansas State University, with 2-year assignment at Ahmadu Bello University, Zaria, Northern Nigeria.

Albert J. Nyberg, Ph.D. Cornell, 1968, Rockefeller Foundation, Nigeria.

Thomas O'Dwyer, Ph.D. Cornell, 1968, Agricultural Institute, Dublin, Ireland.

Erdogan Osmanlioglu, M.S. Missouri, 1968, agricultural economist, Government of Turkey, Ankara.

Luiz Pelligrini, M.S. Purdue, 1968, El Instituto de Economia Rural, Sao Paulo, Brazil.

Javed A. Qureshi, M.S. Maryland, 1968, deputy secretary, Department of Agriculture, West Pakistan.

Rafael Samper, M.S. Purdue, with government in Bogota, Colombia.

Bernard L. Sanders, director of economic and market research, Farmland Industries, Inc., Kansas City, Missouri.

Philip Seaberg, M.S. Wisconsin, 1968, International Milling Company, Minneapolis.

Manu Seetisarn, Ph.D. Illiois, 1968, Department of Land Development, Thailand.

Januk S. Sharma, Ph.D. Illinois, 1968, Uttar Pradesh Agricultural University, India.

Jose S. Silas-Alvarado, Ph.D. Cornell, 1968, consultant for agricultural credit, Bank of Commerce, Mexico.

Michael Thompson, M.S. Illinois, 1968, National Agricultural Advisory Service, Great Britain.

Robert L. Thompson, M.S. Purdue, 1968, International Voluntary Services, Inc., Vientiane, Laos.

Joseph Vandeputte, Ph.D. Illinois, 1968, assistant director of research, Continental Grain Company, New York.

M. Bruce West, M.S. Wyoming, 1968, Statistical Reporting Service, USDA, Sioux Falls, South Dakota.

Earl R. Williams, Ph.D. Tennessee, 1968, assistant professor, Northeastern State College, Tahlequah, Oklahoma.

OTHER LEAVES

Irving F. Davis, Fresno State College, Fresno, California, sabbatical, 1968–69, Instituto Linquistico De Verano, Lima, Peru.

John R. Moore, University of Maryland, 18 months, Ford Foundation, Intensive Agricultural Development Program, India.

OTHER AWARDS

Andrew Schmitz, University of California, Berkeley, the Harold Groves Doctoral Dissertation Award, University of Wisconsin.

OBITUARIES

RICHARD H. ROBERTS, U. S. Agricultural Attache to Canada, passed away at Rimouski, Quebec, October 2, 1968. He had served in the Department of Agriculture for more than 30 years. Prior to entering the Foreign Agricultural Service in 1953, as director of its foreign trade program, Dr. Roberts had served with the Agricultural Adjustment and Production and Marketing Administrations. He had been a delegate to several Food for Freedom conferences and to the Food and Agriculture Organization. A native of Iowa, he received his doctorate from the University of Iowa in 1935.

ELMER JOSEPH WORKING, Professor Emeritus of Agricultural Economics and former chairman of that department at Washington State University, Pullman, Washington, died October 2, 1968, at the University of Colorado Medical Center in Denver, Colorado. Graveside rites were held in Denver. Since his retirement from WSU, Professor and Mrs. Working had lived in Tucson, Arizona.

Dr. Working was born in May, 1900, near Denver, at the Booth-Working homestead where his grandparents had pioneered in 1864. He began his college studies at the University of Denver and was graduated from the University of Arizona in 1921. He received his master's degree at Iowa State University and his doctorate at Harvard University.

He served on the staff of the Brookings Institute in Washington, D.C. and the Bureau of Agricultural Economics, U. S. Department of Agriculture. His early teaching included Iowa State University and the University of Minnesota. From 1935 to 1954, he was professor of agricultural economics at the University of Illinois; in 1954, he returned to the West where he served as chairman of the Department of Agricultural Economics at Washington State University until retirement in 1965. He was subsequently visiting professor at the University of Arizona in Tucson.

Professor Working made numerous contributions to research in agricultural economics. His early article on statistical demand curves is considered a classic in the field of demand and price analysis. It has been described as "a model of penetrating insight, precision of thought, and clarity of presentation."

Dr. Working, a member of Sigma Xi and Phi Kappa Phi, and a Fellow of the Econometric Society, is listed in *Who's Who in America* and other biographical works. He had served as president of the Western Agricultural Economics Association and vice-president of the American Agricultural Economics Association. At its annual meeting in August 1968, AAEA awarded him its highest honor, the designation of Fellow.

Those wishing to remember Dr. Working may send contributions to the Agricultural Economics Memorial Fund, Alumni Office, Compton Union Building, Washington State University, Pullman, Washington 99163, with the notation, "in memory of Dr. Working."

Mrs. Working is living at 5917 East Fourth, Tucson, Arizona.

Selected business firms are invited to become Sustaining Members of the American Agricultural Economics Association. These include firms that have a natural interest in the long-run economic strength of the nation's agriculture. While the association wishes to have the support of these members in all of its activities, they are being particularly looked to for support in the several awards programs being sponsored by the association.

Announcement of the 1969 session of the

ECONOMICS INSTITUTE

Sponsored by the

American Economic Association

in cooperation with the

Institute of International Education
and the University of Colorado

A special transitional training program for selected foreign students who have been admitted to regular graduate study in economics or agricultural economics at universities and colleges in the United States. The purpose is to help students strengthen their preparation and become familiar with United States academic procedures so they may carry on their graduate studies more productively and advantageously. The faculty of the Institute is recruited nationally.

The program includes intensive course work—offered at several levels—in economic theory, quantitative techniques and English. This course work is supplemented by special lectures and seminar series and by field trips and social and recreational activities designed to acquaint the participants with the United States economy and campus and community life. Individual program assignments are determined on the basis of a series of placement tests and interviews.

Location and Dates of Institute

UNIVERSITY OF COLORADO

June 18-August 20, 1969

Admission and Fellowship Information

Final admission to the Institute will be granted only to those students who can provide proof of admission to graduate work in economics or agricultural economics at a university or college in the United States for the academic year following the Institute. Preference is given to applicants who have not previously studied economics in the United States. The Institute is designed primarily for full session participants, but provision is made for the admission of a limited number of applicants for the last five weeks of the program only (i.e., July 16-August 20). Preference is given to single students, to married students who will not be accompanied by any dependents, and to married students (without accompanying children) whose wives also meet the general English language admission requirements of the Institute. All successful applicants falling in these categories (including wives) will be accommodated in the Institute's residential facilities. The admission of others is not precluded but will be conditional upon the applicant being able to arrange satisfactory living facilities for himself and his family independent of the Economics Institute. Applicants and/or their academic year sponsors normally will be expected to pay the full costs of their participation. However, a number of partial cost fellowships will be allotted on a competitive basis to applicants without alternative sources of full financial support. The total enrollment is limited to approximately 100 students. Further details together with admission and fellowship application forms can be obtained from the office of the director.

ECONOMICS OF AGRICULTURAL PRODUCTION, MARKETS, and POLICY

By JOHN P. DOLL, V. JAMES RHODES,
and JERRY G. WEST,
all of *University of Missouri*

Here is the newest, most thorough and intelligible book yet published in the study of agricultural economics. Designed as a basic text, it has supplementary value for courses in agricultural marketing or agricultural policy. Each of the text's three topics—production, markets, and policy—is discussed at length in three separate sections while a unifying theme of economic theory is developed and enlarged throughout.

- **PRODUCTION . . . is devoted to the economics of production on farms, presenting mainly from theory, those topics of particular importance to agricultural production reseach.**
- **MARKETS . . . contains discussion of the structure of markets, the nature of competition among farmers, marketing firms, and food retailers.**
- **POLICY . . . develops the historical and present-day role of government in the agricultural economy and makes application of the theory developed in earlier chapters to government policies.**

570 Pages, Text Price $8.50

READINGS IN THE ECONOMICS OF AGRICULTURE

Edited by Karl A. Fox, *Iowa State University,*
and D. Gale Johnson, *University of Chicago*

This collection provides useful information to graduate students and professional economists who wish to have a general overview of the major analytical problems tackled and methods used by leading agricultural economists in the period subsequent to World War II. This is one of a series of volumes of readings in various fields of economics sponsored by the American Economic Association.

Titles From The Macmillan Company

Modern Breeds of Livestock, Third Edition

By Hilton M. Briggs

This classic text has been revised to reflect current developments and research, and includes material on new and developing breeds, with particular emphasis on the shifting population of various breeds of livestock. Organized on the basis of an historical presentation and evaluation of each breed, the book is designed to acquaint the student with the special attributes and limitations which determine the past importance and future potential of the breeds of livestock generally found in the United States. Charts, tables, and illustrations have been extensively updated.
1969, approx. 752 pages, prob. $12.95

Marketing of Agricultural Products, Third Edition

By Richard L. Kohls, Purdue University

Widely adopted in its previous editions, this basic textbook has been completely updated to keep pace with changes in the organization and functioning of the nation's food marketing system. Changes in the third edition include increased emphasis on market organization and the concept of multiple markets for farm products.
1967, 462 pages, $9.95

Farm Business Management: The Decision-Making Process

By Emery N. Castle and Manning H. Becker, both of
Oregon State University

This study of farm business management presents practical functions and problems of the manager with emphasis on the farm record as an analytical tool. Other topics include economic principles, the matter of risks and uncertainty, and off-farm considerations.
1962, 423 pages, $7.95

Marketing Farm Products

"By far the most widely used book in its field" . . . . says internationally known agriculturist.

Shepherd
Futrell

$9.50

AVAILABLE NOW IN A NEW FIFTH EDITION

* Unique analytical approach applies economic theory to all phases of farm production and marketing.

* This new fifth edition contains revised sections on: food consumption and dietary levels; marketing information; cyclical and seasonal price and production movements; commodity marketing systems and problems for livestock, dairy and poultry products; grains.

* Greatly revised throughout, MARKETING FARM PRODUCTS contains current information on marketing visualized by 50 new or updated tables, 70 new figures and charts.

* Offers studies of the marketing system and how it functions; production and marketing information required to sell at an advantage; cyclical and seasonal price changes; demand, production, and distribution.

* Discusses hedging, decentralized markets, their price surface and influences on price levels, government control programs; grades, values, and prices; over-all costs of marketing and retail distribution.

* Deals with marketing problems associated with specific farm commodities. Gives specific conclusions and offers recommendations.

* *Gives your agricultural economics students the most basic skill of all—sound marketing economics training.*

EDITOR'S NOTE: Professor Shaffer's article was invited by President Breimyer, whose explanation of its purpose is as follows: "This is a base paper for discussions at the annual meeting of AAEA in Lexington, Kentucky, in August, including a panel concluding the meeting. In addition, contributed papers commenting on this paper are invited. Selected ones will be accepted for presentation at the meeting." These papers must adhere to the rules for contributed papers as they were announced in the February *Journal*, except that (for these papers only) the due date is on or before July 1 and only three copies are required. See announcements section for an additional supplementary note on contributed papers.

On Institutional Obsolescence and Innovation—Background for Professional Dialogue on Public Policy*

JAMES DUNCAN SHAFFER

> **"We ourselves must change to master change. We must rethink all our old ideas and beliefs before they capture and destroy us."**
>
> —ROBERT F. KENNEDY

MY concern in this paper is the process of institutional obsolescence and the necessary activity of institutional innovation. The origin of this concern is my perception of a growing discrepancy between the quality of life enjoyed and that which is potentially attainable. My goal is to stimulate professional discussion regarding the institutions which organize our political economy and the possible role of our profession in the process of institutional change.

Let me briefly sketch the design and argument of the paper. Central to the argument is the notion that, while many of the current problems of the American society are those that have been associated with the industrial system and market economy from their origin, the combination of science-originated technology and industrialization (which I will call scientific industrialization) in a state dedicated to economic growth represents an implicit commitment to constant change in the social order. Greater liberation from the constraints of the environment offers new opportunities for human achievements but, at the same time, requires much more complex and adaptable institutional arrangements that add significant new dimensions to the age-old problems of social organization.

I attempt to show that scientific industrialization imposes a necessity

---

* I appreciate comments on an earlier version of the manuscript from H. Breimyer, H. Riley, V. Sorenson, A. Schmid, D. Hathaway, and R. Hildreth, none of whom is responsible for or necessarily agrees with the views expressed.

JAMES DUNCAN SHAFFER *is professor of agricultural economics at Michigan State University.*

for institutional innovation and discuss the introduction of protective institutions. This is followed by an argument that external effects are a pervading problem of the political economy that changes in technology, extent of the market, operating procedures etc., create new patterns of external effects requiring constant institutional adjustment to direct individual efforts to socially desirable ends.

The emerging political economy is the result of the interaction of the processes of scientific industrialization with the political and economic efforts of individuals and groups to take advantage of potential benefits and to achieve protection from the negative effects. A major characteristic has been the development of big bureaucracy, including the giant corporation. Bureaucratic organization is necessary but creates a wide range of policy problems and issues.

Among the policy issues of the emerging political economy are those concerning the organization and control of agriculture, the technological displacement of people and its destructive effects on communities, and the equitable distribution of income. These are briefly discussed, elaborating on the themes developed earlier in the paper.

I conclude with an argument for much greater involvement of applied social scientists in the process of public policy formation. Effective public policy requires management of the evolving system, and effective management requires an understanding of the dynamics of the system. But even more, it depends upon organizing our institutions to direct the system to achieve desired goals rather than accept whatever pattern of organization evolves. An essential input to the system is organized intellectual effort directed at institutional innovation.

In the modern situation, instituting the political economy takes on new meaning *for it is implicit in the scientific industrial system that it at once reduces man's dependence on nature and increases his dependence upon his fellow man.* Breimyer contrasts the industrial and primitive economies. "The primitive is an economy of nature, the industrial an economy of man. The limitations as well as opportunities are tied to nature in the former, man made in the latter. Whether a primitive economy turns out to be good or bad depends upon the bounty or niggardliness of nature—including the native endowments of the aboriginal population; the achievements of an industrial economy are the outcome of the wisdom or the baseness of civilized and educated man" [6, p. 685].

A Motor For Institutional Change

Our fund of ideas about economic dynamics in the industrialization process pretty much dates from Adam Smith's discussion of the pin factory. A basic feature of that innocent precursor of General Motors was the specialization of work roles which takes place in the production and distribution of (1) consumer goods, (2) capital goods, and (3) scientific and technical knowledge. But whereas Smiths example referred to the small scale production of existing consumers' goods—the pins—the greater meaning in the modern context attaches to producers' goods, scientific knowledge, new products, and merchandising. Newly created capital goods and techniques are substituted for existing skills, labor and equipment, rendering existing ones obsolete or of reduced value. The incentive for investing in new technology is the promise of reward [23]. In Smith's idiom the reward came from increased productivity. Today we grant that market advantage (and even tax advantage) can be equally attractive. We can only hope that in most instances there is some addition to productiveness. But, in any case, the result is to alter the level and distribution of incomes, wages and relative prices; also to make a new scale of enterprise appropriate and to create incentives for new patterns of coordination. A new pattern of external effects likewise results, replacing the accustomed pattern, creating an incentive for the development of new institutions of control and protection which are formed in social and political interaction. As a result of experience with new work roles (and locations), new products, advertising, etc., new ways of living evolve, influencing preferences and values. All this creates new incentives, a new round of investment in technology and further specialization. And, in this process a new organization of the political economy emerges.

Although the dynamics of modern society are basically expressed by the process described above, and we need to understand the policy problems associated with them, we must also take care not to become obsessed by technology. The essential derived problem involves social organization, not technology. Veblen and other institutional economists have been quite right to be concerned with the relationship of technology to the institutional organization of society. Nevertheless, the familiar notion that the major problem of society can be stated as institutional lag to technological possibilities seems to involve misplaced emphasis. Institutions are not just a drag on the economy. They represent the efforts of man to organize to achieve a large number of goals, not simply to get more material goods. Technology is a product of institutional organization just as institutional organization is a product of technology.

Adjusting the "Self-Adjusting Market"

Polanyi argues that the liberal state was a creation of the self-adjusting market, and the key to the institutional system of the nineteenth century lay in the laws governing the market economy [19, p. 3]. The founding institutions of the American political economy were based on the concept of a political economy consisting of the self-adjusting market and only sufficient government to protect property and enforce contracts. Jefferson envisaged a system with no concentrations in either economic or political power, with competition among equals in the open market eliminating the inefficient and minimizing the concentrations of power. This arrangement was believed to provide material well-being, foster individual freedom and promote equity.

In considering the evolution of the American political economy it is instructive to consider two modern extreme concepts of "ideal" social organization. The first concept puts emphasis on the self-adjusting market and is characterized by the social goal of maximizing total income of the society. The second would protect the individual and society against all adverse effects of change and is characterized by the goal of maximizing social integration (or minimizing alienation). The first holds that, leaving aside such refinements as second best and optimum growth models, if the economy always meets the marginal conditions necessary for the optimum allocation of resources and at the same time maximum technological advance obtains, incomes of the population will be maximized and this represents the best of all possible worlds.

The second concept of an "ideal" society would maximize social integration and is described by Olson as follows: "The degree of integration tends to increase with the extent to which a set of individuals form a 'community,' and would be nil in a situation in which a set of individuals had no social structure, common values, or institutions. It would be high in a situation in which everyone in a society was tied into the social order by bonds to a wide variety of associations, in which social structure was elaborate, in which common values, norms, and institutions were cherished, where individual roles were well understood, and where mechanisms of social control were well developed. The number and degree of group associations and affiliations, and degree to which behavior is institutionalized or organized, structured, and regularized, tend to be very high, if not indeed at a maximum level in this ideal society" [16, p. 112].

Olson [16] argues that these two models are polar opposites—that the achievement of one would be a nightmare for the other. For to adjust immediately and optimally to every possible change in technical opportunity, as in the income-maximizing ideal, would involve an incessant movement of the factors of production, including labor, not only from firm to firm but from place to place. To achieve this ideal, all group ties would be discouraged, including family ones. By contrast the integration maximizing ideal would lead to economic stagnation, for without changes in work roles there can be no economic growth.

But, of course, neither "ideal" comes close to expressing the full range of human values and goals. Perhaps we should introduce another model which would identify the characteristics necessary for each member to achieve the maximum of his human potential [9]. A part of the policy it is a benefit which cannot be captured, a cost which need not be borne, or a cost or benefit that is not perceived by the decision maker.[1] Abstractly, the problem created by external effects is that those things that each *individual* takes into account in making decisions are so structured that the sum of the decisions do not result in a performance acceptable to the society.

The ideal of the self-adjusting market promised a system of interaction that would coordinate economic activity leading to a desirable product mix in terms of the preferences of consumers. But this begs many essential policy questions. In order for the system to work, institutions of property and control have to be established. And these institutions determine what has to be taken into consideration by individuals and organizations in their economic actions. Much of the conflict of interest in the society is "settled" in the political determination or acceptance of these rules which determine how the desires and preferences of different members of the community are counted. They determine who may benefit from the system and who may not.

New technology, changes in extent of the market, etc., create potential benefits which cannot be captured and costs which need not be borne by firms as currently organized, with existing rules of property and control. Firms respond by attempting to adjust their boundaries of control to gain the potential benefits and to protect themselves from costs imposed by others. And the new pattern of external effects creates the possibility of benefits from new definitions of property rights.[2]

It is the protective institutions which determine to what extent the effects of new technology are internalized. They determine the incidence of the costs of technological displacement. They determine to what extent a firm can protect itself from what Schumpeter called the process of creative destruction, which is the ultimate discipline of the competitive market. It is probably true that no entrepreneur or worker ever exposes himself to marginal return valuation if he can avoid it. The prospects for labor are especially dismal if it is the single factor forced to bear the cost of adjustment [6].

The adjustment to new situations is never simple. There are strong motives to protect against undesired consequences and to gain economic advantage. It is the interaction of these motives with changes in technology, etc., which explains much of the change in the organization of the political economy. It is in this interaction that new institutions are forged.

---

[1] The problem of external effects applies to all organizations of the political economy, not just firms and households.

[2] Demsetz argues that ". . . the emergence of new property rights takes place in response to the desire of the interacting persons for adjusting to new benefit-cost possibilities. . . Property rights develop to internalize externalities when the gains from internalization become larger than the cost of internalization" [8, p. 350]. In his stimulating Fellows lecture, Schultz seems to express this same notion, that there is an equilibrating process which makes it possible to explain institutional changes in terms of the economics of supply and demand [22]. I am concerned that adopting this approach runs the danger of being misunderstood as an apologist for the established order.

Historically the emphasis has been upon the protective institutions which would maximize social integration. The Greeks and medieval thinkers were concerned with the conditions necessary for political and social stability. The medieval guild represented the ultimate in internalization of the effects of new technology by effectively giving the craftsman veto power over the introduction of any innovation. The system was extremely static.

It is Paarlberg's belief that our present rate of technological change exceeds the optimum point. He argues that "the relationship between the rate of technological change in a society and the general good that accrues to the society is in the form of a curve, with a low reading for a semi-stagnant economy, reaching a maximum at some intermediate rate of technological change, and taking on a negative slope when the rate of change exceeds some optimum point. This is contrary to the conventional view, held by almost all physical scientists, that the relationship of rate of technical change in a society and the general good resulting therefrom is positive, linear and steep" [15, p. 15].

I believe the shape of Paarlberg's curve is closely related to a society's capacity to deal with "external effects" of technological change through institutional innovation and compensating public policies. The rate of adoption depends upon the manner in which effects are internalized. Clearly we do not wish to return to the guilds and stagnation. And Hirschman argues that internalizing all effects to a central planning agency is likely "to result in an overestimate of the prospective losses; for it is the nature of most innovations that its beneficiaries are anonymous, inarticulate, and unaware of the benefits-to-accrue (they include among others the consumers that are yet unborn) while those who stand to lose from the innovations are highly vocal vested interests" [13, p. 61].

There are serious external effects, including those related to social instability and community development, that are at least partially outside the accounts of policy makers because they do not have useful measures of them or do not perceive them as within their responsibility. Environmental pollution is an example of a class of serious problems that derive from the introduction of new technology and have effects that are not properly internalized to a decision unit. Some forms of pollution are now so serious that they threaten our survival by triggering irreversible destructive processes in the environment. Every new technology creates the potential for a new pattern of external effects.[3]

---

[3] Let me illustrate some of the elements of the problems of the interaction of in-

Aside from the problems of obtaining evaluations of biological relationships, policy issues involve the assignment of rights. For example, how should we approach the problem of river pollution? The river could be sold to a private corporation. According to our understanding of private property, the owner would then act as a broker between the alternative users of the river, weighing each offer for its use in such a way as to maximize his profit, thus allocating the river to its highest use. This presupposes, of course, that the community would and could protect his right. Or, the river could be treated as communal property with the rights going to anyone who wanted to use it. This actually worked as long as incompatible uses were not competing for the river. The community might declare public ownership and prohibit specific uses of the river or set up a commission to regulate its use. In either case, use would probably be free. To prohibit use for industrial purposes would, of course, affect property values and prices of goods produced. The community could recognize communal rights and attempt to buy clean water by paying users not to pollute. In any case, a new technology, such as an atomic power plant, which adds much heat to a river, will require adjustments in the property

---

stitutions and new technology with a simple story about mosquitoes. Once upon a time a farm community was bothered by mosquitoes and malaria. They did not know the relationship of the two and simply swatted the mosquitoes when irritated, for it was not worth the cost to control them. They next learned that mosquitoes were responsible for malaria. Each farmer could gain some protection by screening his windows, which he did. This had the unexpected effect of making the hardware dealer a relatively wealthy man and thus a man of political power. However, the mosquitoes continued to bite. New knowledge was acquired that linked the number of mosquitoes to the amount of stagnant water. It was determined that if each farmer volunteered 20 hours in the spring, the breeding grounds of the mosquitoes could be drained and the mosquitoes reduced by 90 percent. A new organization was developed, called the Voluntary Mosquito Control Association. It soon became clear to the least ambitious of the farmers that he would be better off by not participating, for he would get the benefits without working. The burden was thus increased on the others, and the process continued until the association failed to function, even though mosquito control was worth far more than 20 hours of work to each farmer. They next attempted a solution by introducing a local ordinance, declaring stagnant water a public nuisance and requiring all land owners to eliminate it from their property. Unfortunately, half the stagnant water was on the land of one farmer. He argued that it was unfair and illegal to impose such cost on him. Since he was also the hardware dealer, and by that time chairman of the township committee on resolutions, the proposal was bottled up in committee. The township board then voted to support a control program through general taxation. This worked well within the township, but, unfortunately, mosquitoes were found to migrate from the next township which had no control program. After several years, a two-township control district was set up and a farmer was granted a contract to control mosquitoes. At this time the new technology of DDT was introduced and DDT was used to kill the mosquitoes. But DDT also found its way to earthworms; and from earthworms to a common bird that was eaten by the cats of a village in the next county. The cats all died, resulting in an invasion of rats which bit the villagers and spread the plague. The villagers then came to understand the damage to them from the use of DDT but had no institution for protecting themselves from the ill effects.

rights since heating the water of the river has not previously been a source of pollution.

The policies selected will make a great deal of difference to the quality of life of the community and to the distribution of income. The choice of policy is complex, requiring a high level of critical analysis. An evaluation of the trade-offs and the full effects of any rules adopted would be required.

The Emerging Political Economy

The Bureaucracies.—If I were called upon to name the emerging political economy after its most obvious characteristic, the name would be bureaucracy. Individuals seek protection through associations—the labor union being a notable example. Trade associations, professional associations, cooperatives, and all kinds of other special interest organizations exist to advance special group interests. The government in attempting to respond to the needs of society develops bureaucratic agencies. And we institute through government a variety of protective rules and income transfer laws, usually interpreted and administered by large agencies. Among these are the rules for group participation in modifying the outcome of market interaction. And perhaps most characteristic of the present age is the bureaucracy which in fact controls and manages the giant corporations.

In our concern for the growing discrepancy between potential and achieved quality of life, we must examine the behavior of bureaucratic organizations. A bureaucracy has among its characteristics the following: It has a life of its own—the incentives perceived by its management may be quite independent of the intentions of its "owners," be they stockholders, legislators, citizens, or members; it spends much of its energy in protective tactics designed for a survival independent of performance [18]; in a changing society, the bounds of control of a bureaucracy frequently become inappropriate to the problems with which it is intended to deal; it is frequently structured to a narrow interest and responsibility, but with capacity for extensive external effects; and it creates positions of extensive power and control, often undisciplined.

Yet, organized technical competence is indispensable to the modern political economy; technology, specialization, and essential protection of society's interests dictate it. We must rethink our ideas of instituting bureaucracies to make them more responsive to the needs of society.

The Corporation.[4]—Berle reminds us that the founding fathers specifically denied the federal government the power to create corporations, because of concern for the potential concentration of power inherent in the corporation [3, p. 76]. Their concern was prophetic. By 1967, the 100 largest corporations held 48 percent of the assets in manufacturing in the U.S. [1, p. 92]. And Berle argues that "if a rather larger group is taken, the statistics would probably show that about two-thirds of the economically productive assets in the United States, excluding agriculture, are owned by a group of not more than five hundred corporations" [3, p. 82]. The control of these giant corporations is in the hands of the managing bureaucracy, with 100 or so trust departments of banks managing very large stock holdings for individuals and pension trust funds with power to check the performance of the management [3]. Surely this represents the greatest concentration of economic power in history. What institutional innovations are needed to insure that this power will be exercised in the public interest?

---

[4] My debt to Galbraith [10], Berle [3], and Mueller and his staff [1] for much of the material used in this section is gratefully acknowledged.

The bureaucracies of the large corporations follow a number of practices (protective institutions) which significantly modify the outcome of the market. They avoid uncertainty and improve vertical coordination through vertical integration and contracts, thus substituting administrative coordination and negotiation for spot market coordination. They have the capacity, within limits set by monopolistic competition, to manage prices. They avoid the uncertainty of the capital market, at least to some extent, by assuring a large part of financing from retained earnings. This gives them significant advantage over small firms. The uncertainties of the labor market are reduced by negotiations with labor unions (thus individual workers avoid marginal evaluation of their effort). Product markets are modified by negotiated contracts with buyers, especially with the government, and by managing consumer demand through advertising, promotion, and product design [10].

According to Galbraith [10], a number of the needs of the corporate bureaucracy are also provided by the state. The state trains technicians and spends large sums on technical research valuable to the expansion of the corporation and the economy. And the state reduces risk to the corporate bureaucracy by providing programs for price stabilization and growth; planning is more successful with a small but regular rate of inflation.

A discussion of the consequences of the developing pattern of larger size firms is beyond the scope of this paper.[5] Let me comment, however, that the evidence is that for most manufacturing industries, the largest firms are much larger than necessary to achieve the economies of scale available in the production process [1, p. 63]; that fostering large size is an unnecessary and unreliable method of stimulating inventive activity [1, p. 67]; and that much of the advantage of very large size relates to financial and promotional activities [1, p. 69].

---

[5] Actually we have no satisfactory evaluation of the performance of the American industrial complex. The test would have to be in terms of comparison with systems controlled by different sets of rules We get some insight into the complexity of the necessary analysis from Sosnick [25], who has recently outlined for us his criteria for effective competition by listing 25 conditions he considers avoidable and undesirable in a market. It would be instructive to test existing markets against his list. He fails, however, to inform us of the necessary changes required to institute markets

We are only beginning to understand the implications of the institutions associated with product differentiation and promotion. They are clearly very significant protective institutions for the firm. Advertising, offering very great economies of scale, is an incentive to larger size and an effective barrier to entry by small firms. And advertising creates a new property in the form of the *image* of the product. Advertising represents about 10 percent of the value added by consumer goods manufacturers [1, p. 69].

Advertising has another dimension in the emerging political economy, since it is designed to change preferences and has substantial effects on the content of the mass media. The concept of the "good life" and acceptable behavior for many Americans is defined in their many hours of exposure to television sponsored by the large advertisers. This is an external effect of firm activities that is of critical importance to the quality of life.

Organization and Control of Agriculture

It is probably true that not more than 12 percent of the value added in the production and distribution of food and fiber in the United States is contributed by farming. The manufacture and distribution of farm inputs, much of food processing, and most of food retailing is done by large corporations or associated groups. The processes of scientific industrialization will continue to create profitable specialization that will result in more activities of food production moving to non-farm occupations and large firms.

Food production and distribution is a vertically coordinated process organized by a complex set of behavioral rules. Nevertheless, it may be of some value to simplify the description of the system in order to get some perspective on the policy issues. For each industry of the sector, the following organizational characteristics can be identified: the extent of horizontal concentration in firm output; the extent of horizontal concentration and bargaining institutions of labor, i.e., collective bargaining with or without government sanction, voluntary or compulsory membership, with or without arbitration; and the relationship of ownership and management—corporation, cooperative, individual proprietor, etc. Activities are vertically coordinated between and within industries by competitive mar-

---

to meet his criteria and the complex effects of such changes in institutions. I leave this to future professional discussions.

kets, negotiation without contract, negotiation with contract, administratively by private or public agency, or some combination or variation of these. Policy analysis is concerned with predicting the performance associated with the various sets of formal rules facilitating or restricting the development of particular combinations of these vertical and horizontal characteristics.

Within the agricultural economics profession, the basic issues of industrial organization and regulation of competition have generally been treated separately from those of price policy and income supports. While the issues of efficiency, equity, and control were being argued in terms of government regulation of farming, a major revolution in the control and coordination of the food and fiber sector has been under way.[6]

As I interpret the political and economic trends, we can expect the specialized protective institutions of price and income supports for farmers to become less important, but at the same time less reliance will be placed on atomistic markets to coordinate activity and evaluate contributions. Laws will be adopted to facilitate collective action by farm labor and farmers. The ultimate form of vertical coordination and control of farming is uncertain. Helmberger suggests "there might be considerable merit in allowing entrepreneurs and competition among them and the competition between conscious and unconscious coordination to specify the best configuration for us" [11, p. 25]. But, this begs the policy question—competition under what rules? The outcome—and thus the performance of the system—will depend upon a large number of institutions, many of which evolved without consideration for their effect on the control or performance of agriculture. And a variety of institutions can be developed that would modify the outcome of the competition among alternative methods of organizing the sector.

For example, a major factor determining the control of farming will be access to capital. The giant corporations have great advantages over other enterprises in access to capital, including large quantities of retained earnings. Would it be a desirable part of agricultural policy to have a 100 percent tax on all *retained* earnings of large corporations? Do price support programs contribute to a division of ownership of land and management in agriculture by increasing land values? Would the development of improved institutions for small corporate ownership, including an effective market for the stock, facilitate control of farming enterprises by those best qualified to manage?

We know that the needs of the industrial system and of consumers create demands for improved specification in product characteristics and timing. Atomistic farm product markets, unregulated as to price or quantities marketed, are generally unstable and unreliable as to supply. The planning needs of individual firms can be met through vertical ownership or by contract. It has generally been assumed that contracts involve direct negotiation and dispense with the market as an allocation mechanism. This is a narrow view of the market. A national market in deliverable forward contracts—using a computer and direct national input through a teleline system, with transportation calculations and brokerage built into the system—could conceivably be established. This would provide the needed coordination and reduce the stimulus for vertical integration into farming, while providing the advantages of a competitive market without the price uncertainty. However, such a market system is not likely to simply evolve. It would have to be instituted through government action.

---

[6] See the excellent set of papers from the joint seminar of the North Central Regional Policy and Marketing Committees entitled "Agricultural Organization in the Modern Industrial Economy" [15].

We know it is unprofitable for individual producers in atomistic competition to promote their products, because they cannot capture the benefits. Advertising, in this case, is a collective good for all those producing the particular product. In contrast, the large corporation selling differentiated products can capture the benefits of promotion. The food analogs—the new substitutes for traditional foods—are developed and produced by large corporations (usually based upon research done at least in part at public expense). Given the power and economies of modern merchandising, it is not unreasonable to assume that an *"inferior"* analog would win in competition with a *"superior"* traditional food. Is it possible that the transition from farm to factory production of food will be accelerated and that consumers will end up with less desirable foods because of the relationships of market structure and advertising? This problem is usually seen only as one involving the freedom of farmers to join or not join a collective association for promotion. But it is more. Where does the public interest lie in this case?

These examples only illustrate that the organization and control of agriculture will be determined by a wide variety of rules of the political economy, although obviously affected by the changing technical relationships.

Technological Displacement and Community

The problem of the people left behind—as so aptly identified by the Commission on Rural Poverty—remains one of the most perplexing problems of political economy. How do we explain and deal with poverty in an affluent society? The very nature of the process of scientific industrialization is to make existing job roles obsolete. The problem has been clear in the United States, with its depressed areas and unemployment coexisting with inflation. It has been the most significant rural adjustment problem in the transition from an agrarian to an industrial society. And millions of people will continue to be affected by the problem in the United

States, some through displacement from farming and many through displacement from other types of employment. In the newly developing areas of the world, the problem is overwhelming. With the newly developed technology in agriculture, tens of millions of people are threatened with technological displacement with little prospect of rapid and effective integration into the economy unless this problem of social organization is solved.

The following quotations illustrate something of the nature of our failure in defining this problem in U.S. agricultural policy.

According to the National Advisory Commission on Food and Fiber, "Overall, the United States has had a highly successful agricultural development policy . . .

"More than anything else, the Federal farm programs of recent years have been attempts to equitably distribute the fruits of agricultural progress to major groups of commercial farmers and consumers. Price supports and income payments have tried to permit farm progress, with its benefits for consumers while retaining some of the gains for farmers" [14, p. 11].

At the same time, the President's National Advisory Commission on Rural Poverty reports that "It is a shocking fact that in the United States today, in what is the richest nation in history, close to 14 million rural Americans are poor, and a high proportion of them are destitute. By their poverty they are deprived of freedom to share in our economic abundance.

We can no longer permit public policy to ignore the rural poor. For if we do, we shall see a continuing movement of rural people to our central cities. As the summer of 1967 illustrated, the slums and ghettoes of the city breed hatred and violence, which is no solution to the problems of either city or country" [20, p. 3].

The contrast in these quotations indicates that our policies of fostering technological development in agriculture and supporting farm prices have had extensive external effects. As too often seems the case, the policy problem was defined and executed in such a way that frequently the most privileged received the most help. Agricultural economists, of course, knew that any program supporting prices would distribute benefits according to output and thus be highly correlated with wealth. Witt reported such an analysis as early as 1942 [26]. And we know that most of the value would be incorporated into the fixed factor, land, thus accentuating the problem. Also, income supports based on historical allotments have essentially the same effect. The marginal farmer and the farm laborer, those most affected by technological displacement, are helped very little, if at all, by these programs and may be hurt to the extent that the programs stimulate more rapid adoption of new methods and capital that replace labor. These programs, appropriate to another period in our history, have long since been obsolete.

We have tended to consider technological displacement as a problem of individual adjustment for those who are displaced. Economists tend to emphasize programs to facilitate mobility of the individual as a worker. We have had a number of institutions to ease the adjustment or to protect individual workers. On the other hand, some of our accepted protective institutions have the effect of making it more difficult for those who have been displaced—those most in need—to participate in the economy. Examples are entry restrictions of unions, pension schemes that make it uneconomical to hire older workers, minimum wage, and a host of credential requirements unrelated to performance.

Our protective institutions have been far from satisfactory in providing the positive values associated with social integration and human development. Our associations and governmental units have tended to become large bureaucracies, often contributing to rather than reducing alienation. Our welfare programs have tended to be degrading and alienating, rather than integrative. Even many of our schools, society's greatest hope for fostering human development and socially productive attitudes, have become large, impersonal alienating organizations. Communities in both urban and rural areas continue to be disrupted as people migrate in response to market and welfare incentives.

The problem has been accentuated by a host of obsolete institutions and organizational boundaries among our local governmental units. An example is the property tax as a major source of revenue for education and local government. It belongs to another era. In combination with several related institutions, it is contributing to a process that is destroying many communities and disadvantaging thousands of young people.[7]

---

[7] Let me illustrate. New technology in cotton results in a migration of some poor people from the south to a northern city. The new arrivals settle in an old but respectable area of the city. They send their children to the school. Since they came from an area with little schooling, the new children increase the cost of maintaining existing standards in the school. The school adminisrators attempt to meet the new needs by program changes requiring additional money. The only source of additional money is the local property tax, a tax well suited to an agrarian society, but obsolete today. The tax election passes the first time, but provides insufficient revenue to maintain the quality of the school. In order to get better schools and to avoid the high taxes of the city, some of the older residents of the city move to suburbia. New migrants move into vacated homes now owned by corporations interested in maximizing profits. The suburbanites put pressure on the legislature to build highways into the city in order to get them to their jobs in the city. This adds to the city budget and at the same time takes property off the tax rolls. Since the road went through the poorest part of town to save money, the demand for low cost housing increases. Property taxes go up. The landlords and home owners find that any improvements they make in their homes cost them large sums in additional property taxes so few improvements are made. The atmosphere of the city deteriorates. More of the middle class desert the city. Property taxes go up. Slums develop. No increased property tax to support schools can be passed because it imposes a high burden on low income people and those who put highest value on education have left the city. The social fabric of the city also deteriorates. The boundaries of the city are fixed and it cannot save itself. A bill is introduced in the state legislature to get state-wide support for

The external effects involved in displacement and more generally in the pattern of human settlement have been largely disregarded. The environment of the community—including the attitudes of its people—is a collective good. A quality environment requires collective action. New planning concepts and procedures for collective decision making must be developed. The political economy of community development has been seriously neglected.

Income Distribution and the "New Property"

Many of our values supporting the institutions that specify claims to income were developed in an agrarian society where the property rights to land were very important. If no ownership rights exist in the land, there is usually inadequate incentive for a farmer or hunter to husband the land [8]. In an agrarian economy, the man working the soil saw a direct relationship between his sweat and his return. And, in an economy close to subsistence, it was important that this connection be ever maintained. Thus, the habit of thought that income received was earned and was rightfully due had high social utility. The equity issue arose only in regard to the distribution of land. In the modern economy, however, many of the protective institutions represent claims upon income or can be used to gain income advantages with little relationship to productivity.

Whereas in the agrarian economy much of the increased productivity was imputed to the fixed factor land, today it is imputed to a wide variety of intangibles or vested rights—the new property—including corporate stocks, strategic positions in corporations, tenured positions, union memberships, licenses, quotas, brand names, educational credentials, as well as property rights in natural resources. And, of course, much of the increased productivity accrues to those with special skills and information—those in whom a part of our accumulated knowledge has been vested.

It has always been true that productivity depended upon technique. However, in the modern industrial economy, knowledge and organization have become the *dominant* factors in production. To a very large extent, the wealth—or productive capacity—of the U.S. economy lies in the accumulated knowledge of the society. It is clearly urgent that we modify our institutions to achieve a more equitable sharing of the increased productivity, based upon our inherited knowledge.

---

schools and eliminate the property tax. But the chairman of the tax committee, a suburbanite of long standing, refuses to allow the bill to be debated. Finally, in frustration, the city burns.

The property tax is having the same effect on the rural community. The educationally disadvantaged in the United States reside in rural areas and the inner city. They will continue to be disadvantaged as long as the property tax remains the only source for the quality differential in education. And the consequences will be felt in the quality of life of all of us.

The legitimacy of the present system is being seriously challenged and is a factor in the political and social instability we are experiencing. Greatly increased productivity is in the offing. The rules of the game give great differential advantage in access to this increased income, and everyone more or less has come to recognize that the increase is not due to the anguished sweat of individual workers or the astuteness of management, but to the level of technical capacity in the total system.[8]

We should be reminded, of course, that income distribution and level and quality of output of the political economy can never be separated. For the pattern of institutions which determines the distribution of income also structures the incentive system. That is, income distribution and levels and quality of output (including social stability, etc.) of the total political economy are joint products. This is not to say that we cannot have both greater output and more equitable divison of income, for we surely can. Our problem is to develop the appropriate institutions.

There is much evidence that many Americans seek a more equitable system. The sense of community has resulted in literally hundreds of protective rules, organized programs of grants[9] and related taxes intended to help the relatively disadvantaged. But many of the programs and protective laws have been ineffective, often self-defeating, and sometimes destructive of their intended purpose.

Without significant institutional modifications, the problem will likely worsen. Even with grants and income taxes, there appears to have been little change in income distribution in the United States in the last 25 years. This means that the absolute differences in income are becoming much larger. With more and more workers organized, with greater vulnerability of the system to organized groups, and with more large scale firms, the struggle of each group to get its "fair share" will make it even more difficult for the unorganized and unpropertied to share in the increase.

---

[8] Ayers argues that economists use the concept of productivity and the theory of marginal productivity (including the conclusion that "Free competition tends to give labor what labor creates, to capitalists what capital creates, and to entrepreneures what the coordinating function creates") as an ideological support for the existing system of income distribution [2, p. 3]. I agree with Hirsch, however, that this is an unfair attack on economists [12]. Yet, the habits of thought associated with the marginal productivity theory do serve to support existing patterns of income distribution and impute a meaning that the theory never justified. We talk of wage increases being justified by increases in productivity and imply that differences in incomes received by those with different levels of education represent differences in contribution. It is also clear that some economists and many members of the public believe that any income distribution which obtains from a "free" market does reflect the patterns of contribution and, thus, the incomes are ethically justified.

[9] Grants have increased from something like 3 percent of GNP in 1910 to something between 10 and 20 percent today, depending on definition. Grants are an important aspect of the evolving system; hopefully, understanding of their role will be enhanced through a new association for the study of the grants economy [5].

We need to find an effective way of legitimizing a flow of income to the relatively disadvantaged and to make our intangible property socially more beneficial. Grants are useful as incentives for participation in activities beneficial to individual development and community. However, the creation of new rights would have significant advantages over grants as a means of providing access to income.

One of the problems of the present welfare system is that, notwithstanding the general question of equity, once income is received it is considered earned and deserved by the receiver. And taxpayers are resistant to giving up their "hard earned" money and have it transferred to those without "legitimate" claim.

Let me suggest for *study* an alternative which meets some of the needed characteristics. It is anything but a complete idea.

A new organization would be created—let's call it the U.S. Inheritance Mutual Fund. USIMF would be an independent mutual trust organization which would own, in the name of the citizens, certain income earning assets. It would own the rights of all scientific discoveries, inventions, and commercially exploitable ideas which derive from the work of scientists and technicians supported by government funds. The federal expenditures for scientific research and development in the 1960's will be in the range of $150 billion. And the rights to certain past technological developments would also be awarded to USIMF. The fund would not itself exploit the processes commercially but would license their use. In addition, the rights to certain of the existing public properties would be vested in the fund. In any situation where the government, for whatever other purposes, creates a monopoly or special privilege or windfall gain, the access to that monopoly or privilege would be competitive bidding and the rights to the income obtained would belong to the fund. For example, commercial TV channels would be offered to the highest bidder meeting specified performance criteria. All inheritance taxes would also go to USIMF. The trustees of USIMF would be instructed to transfer as much of the fund's wealth as would be prudent into stocks of American industry. The Congress would write the "will" specifying that all citizens had inherited the wealth of the fund and would share in it according to specified criteria of age and family composition. The amount of the payment each month would depend upon the earnings of the fund.

I make no special plea for this particular institutional innovation, although I believe it suggests some interesting possibilities. We do not have a very good idea of the potential effects of such an institution on incentives [17]. It should promote respect for self and the American system. It eliminates some of the bureaucratic problems in the present welfare system. It would not stimulate migration to gain welfare advantages. If, in instituting the innovation, political trade-offs could be made to eliminate many of the discriminatory and obsolete protective institutions and this would be complemented by a positive approach to the problems of community and human development, we might just move in the direction of the "best of all possible worlds."

On the Role of Applied Social Scientists

Public policy is concerned with changes in the formal rules that regulate the activities of members of the society. These rules specify rights and obligations. By and large, the social science disciplines have taken the position that these rules cannot be judged. They are the province of ethics and moral philosophy. But surely the rules of the political economy must be judged, and I believe that applied social scientists have a major role to play in the process.

Alternative rules lead to different consequences. It is the province of applied social science to understand the complex social systems and predict the consequences of alternative sets of rules. The purist may argue that as scientists, the appropriate role is to simply identify relationships and specify alternative outcomes leaving the value judgments to the political process. Ultimately, in a democratic society, the judgments of value are and should be made in the political process. But, this does not interpret the role of applied social scientists. Both the issues selected and the variables included in analysis involve value judgments. So, like it or not, the social scientist involved in policy analysis becomes a participant in the process, bringing his value judgments with his analysis.

The variables considered relevant in any policy issue will clearly affect any predictions made. To a large extent, the variables considered relevant are determined by the discipline of the social scientists. And, the very high levels of specialization by the different social science disciplines bring a narrow perspective to their analysis, greatly reducing the effectiveness of social science in policy formulation. A part of the present problem in U.S. public policy is the failure to consider the essential variables involved in our critical policy issues. For example, the sociologist's basic question concerning the factors that hold the society together must be considered along with the questions about *economic* growth.[10] Too many of our socio-economic policies have effects quite unintended by the policy makers.[11]

---

[10] Senator Mondale and several other senators have introduced a bill to be known as the Full Opportunity and Social Accounting Act which would provide for a Council of Social Advisors, presumably to parallel the Council of Economic Advisors. Among other activities the new council would be expected to interpret social indicators to policymakers [16]. This is a welcome proposal but I believe the two councils should be integrated, with a requirement that serious attention be given to the development of a unified report that would provide a balanced evaluation of the trends in the quality of American life.

Prediction of consequences depends upon description of the system, which can be approached as an activity of pure science. In this connection, I have been wondering if the habits of thought imposed by our equilibrium models may not restrict an understanding of the complex evolving system. Buckley contrasts equilibrium, homeostatic, and complex adaptive models, describing the latter in part as ". . . open 'internally' as well as externally in that the interchanges among their components may result in significant changes in the nature of the components themselves with important consequences for the system as a whole . . . True feedback loops make possible not only self-regulation, but self-direction or, at least, adaptation to a changing environment, such that the system may change or elaborate its structure as a condition of survival or viability" [7, p. 490]. Buckley argues that the socio-cultural system more closely fits the complex adaptive model. I do not believe the dynamic system can be described by equilibrium models or theories of advantage. We need also accept the fact that the system is too complex to ever completely specify, and we will have to live with a fairly high level of uncertainty as to outcome of the dynamic system.

Description of the complex adaptive system and prediction of the flow of consequences from alternative policy proposals, in my view, does not describe the full role of social scientists in our democratic society. I believe a substantial effort should be spent in diagnosis of society's ills and prescription of institutional innovations to deal with the problems [24]. Prescription involves art as well as science. We need to develop the skill to create the concepts of new institutions that will serve the purposes of society. For social scientists of this persuasion, this means being a social critic. *The universities should nurture the social critic and support extensive dialogue on issues of public policy, as should the academic professional associations. It is an essential input to the development of the emerging society.* And university professors need much more aggressively to perform this essential social function. We need to bring organized trained intellectual resources to this task. Among other things, we must learn to institute effective task forces to deal with the larger, more complex problems of public policy. Reform cannot be left to the uninformed.

This role is, of course, made more difficult, and at once more important, by the fact that there is no simple harmony of interest in society. The social scientists can do much to explain policies of long run mutual advantage and this has not been fully exploited. However, it is seldom that significant changes in rules would receive unanimous vote of the population, which is the implied requirement for Pareto optimality. The role of social critic is made all the more important by the domination of society by only partially disciplined bureaucracies and by the extensive concentrations of power with strategically situated vested interests. Our forefathers emphasized the need for a balance of power, and in this the university has a very important role to play.

---

[11] Would it not be desirable to institute an independent agency of applied social scientists, responsible directly to Congress, to provide an effective and continuous evaluation of the acts of Congress? I believe so, although this would put some power of government in this agency because information as well as power makes policy.

In our society, research and development means, by and large, technical research and product development. We have failed to convince the policy makers of the necessity for extensive research and development designed to improve the social institutions. Thus, our first task is clearly educational. We must teach students and the public about the social consequences of the evolving scientific industrial system and the necessity for orderly reform.

The old habits of thought, which assume that leisurely processes of judicial and legislative review are adequate to meet the opportunities and problems created by newly developed technology, are obsolete. We know the time between a scientific discovery and its application is steadily declining. The rate of technological innovation could increase enormously. A system for anticipating the negative effects of a new technology is sorely needed. We cannot afford to wait for the problem before solving it. *The institutional innovations will have to be developed as joint products with the technology.*[12]

Implicit in my argument is a call for a reorientation of some of the activities of agricultural economists. Just as the work roles of others in the economy must change as the political economy evolves, so it is with our own. Bishop was properly concerned that "To continue on the road we have been traveling will likely lead us into the role of publicly subsidized consultants to the corporate farms and marketing firms of the future" [4, p. 1007]. But I believe agricultural economists come as close as any group to having the background and attitudes needed for effective participation in the research and extension activities required for evaluating existing institutions and developing improved institutions. We have always been oriented to helping people solve their problems; today, the critical problems involve institutional reform. We may be especially effective in helping to vitalize the institutions of the rural communities.

We need to re-examine our training of graduate students. Can we train them so that they will develop the unified approach to social science so essential for work in public policy and community development? We are not doing it now. And is it necessary for each of them to be trained as applied mathematicians and formal systems model builders? Are there not those who would better study ethics, law, and the other social sciences as preparation for institution building rather than model building? I believe we need both.

---

[12] For example, there are special problems of allocating rights where a threshhold is involved. Suppose it were determined that x millions of tons of DDT could be used in the world with no adverse effects and that 2x would kill most of the fish in the ocean. How ought the right to use DDT be allocated under these circumstances?

Our technology has liberated us from the base tyranny of the environment, but we have not adjusted to the new freedom with its implicit premise that a meaningful life for all the members of our society is limited only by our will and creativity in structuring our institutions.

The International Encyclopedia of the Social Sciences: A Review Article*

JAMES P. CAVIN

ACCORDING to the editor's introduction, "The *International Encyclopedia of the Social Sciences* is a completely new reference work, designed to complement, not to supplant, its predecessor, the *Encyclopedia of the Social Sciences.*"

It is obvious that an encyclopedia cannot be reviewed in the conventional sense. Indeed it can be argued that a review is superfluous. Congenital users will consult it anyway; nonusers will ignore it. However, having accepted the responsibility for a review, I must proceed forthwith. In view of the interests of this Association and the limitations of space, the focus is mainly on the economics component of these volumes. When referring to articles, I have generally cited the volume and the author. I have not given the author's academic or other affiliation except when from a country other than the United States.

With the social sciences becoming increasingly quantitative, it seems appropriate to begin with a few facts and figures. The *International Encyclopedia* contains 1,716 articles (including about 600 biographies) prepared by over 1,500 scholars—all but a few of whom are social scientists. It adds up to over 9,000 pages and about 8 million words. It fills 17 large volumes—the last being an exhaustive index. The delivered weight is 82 pounds. The enterprise is also substantial from the financial point of view, as evidenced by an initial outlay of $2 million by the publishers.

The simultaneous publication of all 17 volumes is an impressive editorial feat, particularly when one recalls that its predecessor was issued volume by volume during the years 1930 to 1935 [2]. The editor is David L. Sills of the Bureau of Applied Social Research, Columbia University, assisted by 7 associate editors and 5 special editors. The associate editor for economics is Albert Rees of Princeton. The special editors include Bert F. Hoselitz of Chicago, for economic growth, and Robert H. Strotz of Northwestern, for econometrics. Overall guidance was provided by an Editorial Advisory Board of 175 eminent scholars, under the chairmanship of W. Allen Wallis, president of the University of Rochester. Alvin Johnson—associate editor of the 1930–35 encyclopedia—served as honorary editor.

---

* Sills, David L., ed., *International Encyclopedia of the Social Sciences,* 17 vols. New York, The Macmillan Company and the Free Press, 1968, xxx + 9,750 pp. ($495, the set).

JAMES P. CAVIN *is retired from the USDA and is consultant to several organizations and agencies.*

The planning and organization of both undertakings have a most interesting and illuminating history. Users of the present volumes can profit by reading the Foreword by Johnson, the Preface by Wallis, and the Introduction by Sills.

An important difference between the initial effort and this one concerns the scope of the social sciences. In the first version, the editor-in-chief—the late E. R. A. Seligman—admitted 7 disciplines to the realm: politics, economics, law, anthropology, sociology, penology, and social work. He also identified 4 semi-social sciences—ethics, education, philosophy and psychology—certain aspects of which were covered because of their increasing significance for social problems. Lastly, a number of sciences with social implications—biology, geography, medicine, linguistics, and art—were accorded marginal attention.

The *International Encyclopedia* embraces 10 disciplines: anthropology, economics, geography (in its non-physical aspects), history, law, political science, psychiatry, psychology, sociology, and statistics. The last field is not regarded as a social science *per se* but as a "critical auxiliary discipline" on which the social sciences are increasingly dependent. Emphasis is placed on the analytical and comparative aspects of the several disciplines rather than on historical and descriptive materials. The 600 biographies compare with some 4,000 in the first encyclopedia, but the new ones are generally longer and include a few living persons.

The basic organization is alphabetical—from Ability to Zoosemiotics—modified appreciably by the frequent grouping of several articles under one alphabetical heading. For example, 10 separate articles are grouped under Agriculture, 6 under Anthropology, 4 under Economic Growth, and 8 under History. These groupings are variable in nature and extent, and appear to reflect the considerable degree of autonomy enjoyed by the associate and special editors in organizing the contributions within their respective subject matter fields.

Essential to any encyclopedia is a good index, and here the editors have done about all that one could ask. In addition to a detailed general index of over 300 pages, they have provided an index of authors, an alphabetical listing of articles, and a classified list of topical and biographical articles. The latter are arranged under 29 headings, such as Anthropology, Econometrics, Political Science, and Sociology. To take one example, some 75 subject matter articles and 39 biographies are listed under Statistics. The user can see at a glance that he will find articles on the design of experiments, correlation, game theory, sequential analysis, Markov chains, and time series, as well as biographies of Karl Pearson, Abraham Wald, R. A. Fisher, G. Udny Yule, and others.

This is probably as good a place as any to note that the typography is excellent, the bibliographies exceptionally well presented, and the volumes lie flat when opened. These technicalities greatly enhance the usefulness of the encyclopedia. Typographical errors appear to be rare. There is one in Vol. 10, p. 452. Also, in Vol. 4, p. 351, H. L. Moore's middle name is given as Luddell instead of Ludwell.

A large proportion of the articles concerned directly with agriculture are included in the 10 groups under that heading (Vol. 1): "Comparative Technology," by F. H. Farmer (St. John's College, Cambridge); "Social Organization," by Charles P. Loomis; "History," by Wilhelm Abel (Göttingen); "Production," by Dale E. Hathaway; "Capital," by Glenn L. Johnson; "Labor," by Varden Fuller; "Productivity," by Zvi Griliches; "Marketing," by Herman M. Southworth; "Price and Income Policies," by D. Gale Johnson; and "Developing Countries," by John W. Mellor.

Land also receives considerable attention (Vol. 8). Two articles are grouped under that heading: "Economic Uses," by Marion Clawson, and "Classification," by L. Dudley Stamp (London School of Economics). Grouped under Land Tenure are "Introduction," by Daniel P. Biebuyck; "Agricultural Tenancy," by John F. Timmons; and "Land Reform," by Philip M. Raup.

Other references to agriculture, land, and related topics can be located readily in the general index. Since the articles under Agriculture total only about 60 pages and those on Land about 25, their appraisal can surely be left to the individual initiative of readers of this Journal.

Gale Johnson's article on price and income policies—which takes a rather dim view of the whole business—serves to remind one that this topic has become progressively less important as a focus of agricultural economics research in the United States. It seems clear that neither Congress nor farm groups will accept anything resembling a free-market solution; but neither will they accept stringent and comprehensive controls, such as those advocated some years back by Willard Cochrane [1]. As a result, we continue to lumber along with various rearrangements of the vintage mixture of price supports, direct payments, acreage allotments, land retirement, surplus disposal and import restrictions—with the probability that the land retirement approach will receive increased emphasis under the Nixon administration.

Two areas prominent in this encyclopedia, namely Economic Growth and Econometrics, should be of considerable interest to most agricultural economists. The four articles under the heading of Economic Growth (Vol. 4) complement each other exceptionally well. "Overview," by Richard A. Easterlin, develops the central theme that "economic growth is a creature of the scientific revolution." "Theory," by Gustav Ranis, has an historical emphasis extending from the classicial economists to the Harrod-Domar model and its variants. "Mathematical Theory," by Michio Morishima (Osaka University), gives special attention to the models of

Walras and Von Neuman. The last article, "Noneconomic Aspects," by Bert F. Hoselitz, special editor for economic growth, emphasizes the "social and cultural aspects of the condition of underdevelopment."

These four articles, together with a number of others—including that of Mellor mentioned above, "Capital, Human" (Vol. 2), by Theodore Schultz, and "Economy, Dual" (Vol. 4), by W. F. Wertheim of the University of Amsterdam—provide a solid introduction to the field as a whole. The last article contains an interesting summary of the theories of Boecke, the Dutch economist, and Geertz, the American cultural anthropologist, on the persistence of underdevelopment in the economies of a number of Asian countries.

Articles on, or related to, econometrics are abundant, to be found not only under the heading Econometrics, but under Statistics and Methodology as well. Only a few examples can be cited here to indicate the scope and nature of the contributions in these areas.

A comprehensive survey of the development of Econometrics (Vol. 4) is provided by Robert H. Strotz, the special editor for this field. Two articles that should be of particular interest to readers of this Journal appear under the heading of Demand and Supply (Vol. 4)—one, a theoretical article by Kenneth E. Boulding; the other, "Econometric Studies," by Karl Fox, who gives special recognition to the contributions of agricultural economists, including Mordecai Ezekiel, Elmer Working, Fred Waugh, George Brandow and Earl Heady.

To no one's surprise, "Input-Output Analysis" (Vol. 17) is handled authoritatively by Wassily Leontieff. Other articles include "Mathematical Programming" (Vol. 12), by Richard E. Quandt; "Simultaneous Equation Estimation" (Vol. 14), by Lawrence E. Klein; and "Distributed Lags" (Vol. 4), by Marc Nerlove. Four substantial articles will also be found under Time Series (Vol. 16): a general discussion by Gerhard Tintner; "Advanced Problems," by P. Whittle (University of Cambridge); "Cycles," by Herman Wold (University of Uppsala); and "Seasonal Adjustment," by Julius Shiskin.

The foregoing are but a small sample of the total, which constitutes a smorgasbord of high quality from which users of these volumes can choose according to their interests, needs, and mathematical competence.

For those interested in some of the perennial problems of theory, there are numerous attractions. The following group provides some examples: "Economies of Scale" (Vol. 4), by Joe S. Bain; "Welfare Economics" (Vol. 16), by E. J. Mishan (London School); "Economic Equilibrium" (Vol. 4), by Kenneth J. Arrow; and "Utility" (Vol. 16), by Nicholas Georgescu-Roegen.

The first two articles are brief and not overly technical. I found Mishan's conclusions especially interesting. He says that "it would be optimistic to expect that continued study of welfare economics will contribute toward making the world a happier place." Nevertheless, he believes that it "can do much to mitigate some of the more blatant ills of the affluent society by combating conservative presumption in favor of commercial criteria and by revealing manifest injustices in any price system that has not been corrected to make allowance for visible and widespread external diseconomies."

Arrow's presentation combines a history of the concept of equilibrium with an exposition of recent contributions, including his own and those of Wold, Hicks, Samuelson, and Debreu. The article by Georgescu-Roegen, who has been described by Samuelson as "a scholar's scholar and an economist's economist" [3], covers 30 pages plus an exhaustive bibliography. Virtually every important contribution from the Greeks to 1966 is included, accompanied by numerous equations, relations, and diagrams. It is truly impressive. For anyone who wishes to join in the seemingly endless struggle with the problem of value, this is unquestionably the place to start. It is particularly recommended to those who accept the "dogma of interpersonal noncomparability of utility," with respect to which the last section is especially pertinent. Though these last two articles are of primary interest to mathematical economists, those with only modest mathematical equipment (such as this reviewer) can learn a great deal from them.

A fair number of articles involve, in various degrees, the interaction of theory, measurement, and policy. Two examples, which bear on current controversies over the causes and cures of inflation, are "Inflation and Deflation" (Vol. 7), by Marvin Brofenbrenner, and "Quantity Theory" (Vol. 10: Money), by Milton Friedman.

Friedman outlines the history of the quantity theory, the Keynsian attack, and the subsequent reformulation. He also summarizes empirical evidence concerning the relation between changes in the quantity of money and changes in the price level. His policy conclusion is that "inflation can be prevented if and only if the stock of money per unit of output can be kept from increasing appreciably. Deflation can be prevented if and only if the stock of money per unit of output can be kept from decreasing appreciably." Altogether, this is the best presentation of Friedman's views that I have seen. Brofenbrenner discusses the problem of price level measurement; presents the major theories of price level movement with a number of effective diagrams; looks at some of the empirical evidence; and gives special attention to the redistributive effects of inflation on income and wealth.

The group of three articles on Index Numbers (Vol. 7) is also relevant. These are "Theoretical Aspects," by Eric Ruist (Stockholm School of Economics), "Practical Applications," by Ethel D. Hoover, and "Sampling," by Philip D. McCarthy.

A considerable proportion of the articles mentioned so far have a high mathematical content. However, this should not be allowed to obscure the fact that important areas of economics require descriptive-historical investigation and appraisal of ideologies, institutions, and policies. Examples are "Capitalism" (Vol. 2), by Calvin Hoover; "Welfare State" (Vol. 16), by Harry K. Girvetz; "Corporation" (Vol. 2), by Edward S. Mason; "Laissez-Faire" (Vol. 8), by H. Scott Gordon; and "Socialism" (Vol. 14), by Daniel Bell.

Hoover provides a clear and well-balanced account of the origins of modern capitalism, concluding that the traditional distinctions between capitalism and socialism have become blurred. Similarly, Girvetz traces the rise of the welfare state. He concludes that "there are no signs, outside of marginal groups centered in the United States, of a disposition to curb the welfare state. It rides the wave of the future." Mason shows that the modern corporation is not the simple creature of the legal textbooks, but a complex and evolving institution, whose functioning is not fully understood. Among other things, he points out that we lack "a clear and persuasive account of managerial motivation and behavior." Bell's excellent survey of socialism runs to 30 pages. Not only does it trace changes in the ideologies of the principal socialist thinkers from the beginning, but provides a country-by-country account of the socialist movement between the two world wars and in the present post-war period. Gordon's brief summary of laissez-faire is the best I know.

The biographies deserve more than passing notice, but here again comments must be brief. Generally speaking, they are intrinsically more interesting than technical articles, and I sympathize with the member of the Editorial Advisory Committee who recommended that the encyclopedia contain *only* biographies, on the grounds that these are all that anyone ever reads.

The decision to make the biographies longer than those in the 1930-35 volumes has been well justified. It enabled each writer to provide a more substantial account of the contributions of his subject and his place in the development of the various disciplines. This is well illustrated in the biographies of such greats as J. M. Keynes, by R. F. Harrod (Oxford); Alfred Marshall, by Bernard Corry (London School); Léon Walras, by William Jaffé; Vilfredo Pareto, by Maurice Allais (École Nationale Supérieure des Mines de Paris); Émile Durkheim, by Talcott Parsons; Max Weber, by Reinhard Bendix; and Sigmund Freud, by Robert R. Holt.

I was personally gratified to find biographies of Meyer Girshick (Vol.

6), by Kenneth Arrow, and A. P. Usher (Vol. 16), by J. H. Dales (Toronto). Girshick was not only a gifted statistician, as his peers have testified, but also a man beloved by all of his colleagues in the old Bureau of Agricultural Economics. Usher was one of my favorite professors—a stimulating teacher and a generous counselor.

Allowing for duplication, about 160 biographies are listed under economics, econometrics or economic history. These are all logical choices, though I am sure that most economists will readily think of others who might well have been included. On my list is Edwin F. Gay, described by Fritz Redlich in his biography of N. S. B. Gras (Vol. 6) as "America's first economic historian." It might also be noted that Gay, along with Jacob H. Hollander and Edwin G. Nourse, was one of the three editors for economics in the first *Encyclopedia of the Social Sciences.* One Fellow of the AAEA rates a biography: Thomas Nixon Carver (Vol. 2), by Overton H. Taylor, who mentions his "important pioneering work in the economics of agriculture." In my opinion, there are at least three or four other Fellows (living or dead) who would merit inclusion.

As to some general considerations, it may be recalled that the 1930-35 encyclopedia contained about 250 pages of introductory essays on the scope of the social sciences and the historical development of social thought and institutions. I believe that the usefulness of the present volumes would have been enhanced by similar essays summarizing progress from the Great Depression to the present, although the tight schedule under which this encyclopedia was completed might well have precluded such an addition. There are a number of articles, however, that touch on the more recent development of some of the disciplines. These include: under Anthropology, "The Field" (Vol. 1), by Joseph H. Greenberg; under Sociology, "The Development of Sociological Thought" (Vol. 15), by Shmuel N. Eisenstadt (The Hebrew University); "International Relations" (Vol. 8), by Chadwick P. Alger; "Political Science" (Vol. 12), by David Easton; and under Statistics, "The History of Statistical Methods" (Vol. 15), by M. G. Kendall (CEIR-London).

I think there have been at least four major developments in economics during the period in question. The first is the pervasive influence of John Maynard Keynes. The 1930-35 volumes refer to his *Treatise on Money,* but the *Theory of Employment, Interest and Money* was yet to come in 1936, bringing in its train the Keynsian Revolution and the New Economics. Articles in the present encyclopedia abound in references to such concepts as involuntary unemployment, the consumption function, liquidity preference, the investment function, and the multiplier—terms not found in the earlier volumes.

A second development has been the vast accumulation of economic data. Richard Ruggles in his article, "General," under Economic Data

(Vol. 4), identifies the main types as the national income accounts, flow-of-funds data, input-output data, and statistics on national wealth. Here again the hand of Lord Keynes is evident. As Ruggles states, he "fostered the concept of economic data as a systematic body of interrelated information." This list could well be supplemented by statistics in such areas as population, labor (including employment and unemployment), and food consumption.

Next comes the surge of mathematical economics and econometrics. To quote Samuelson, "In the middle third of the twentieth century, mathematics has everywhere swept through economics like an epidemic of measles sweeping through a new continent" [3]. In retrospect, Oskar Morgenstern's statement in the 1930-35 volumes appears modest indeed. He wrote (Vol. 5, p. 358): "In the future an increasing use of mathematics for purposes of both deduction and induction may be confidently expected." Of course, this use reflects not only the greater mathematical competence of economists, but also the proliferation of economic data just mentioned and the great advances in statistical methodology.

Lastly, there is a renewed concern with problems of economic policy. Economists (particularly those familiar with economic data and skilled in quantitative analysis) are being called on for help in such areas as housing, medical care, environmental pollution, economic development of poor countries, international monetary reform, and domestic wage and price policies. These activities extend to service on task forces of presidential candidates, as well as on or for the President's Council of Economic Advisers. In this connection, Herbert Stein, author of an article under Fiscal Policy, "Overview" (Vol. 5), and H. S. Houthakker, author of the biography of Ernst Engel (Vol. 5), have been named members of the new Council.

This trend seems all to the good, though some may disagree. It serves to maintain the vital link between research and critical economic problems; to test the workability of policies implied or expressed in existing studies; and to increase the relevance of future research. In short, it should help to counteract what Ben B. Seligman has termed the "thrust toward technique for its own sake" [4].

Though the great influence of Lord Keynes has been emphasized, Smith, Ricardo, Mill and Marshall are still important and, with the mathematization of economics, the stars of Walras, Pareto, and Irving Fisher are steadily rising. Even the almost forgotten Simon Newcomb has reappeared on the horizon.

I have no special qualifications for appraising the influence of pioneers in the other social sciences. However, it is evident that Freud still dominates the fields of psychology and psychiatry, although the influence of Jung is increasingly felt. Durkheim and Max Weber are still giants in sociological thought. Just who is who in anthropology is difficult for the nonspecialist to discern, but it is clear that the discipline still owes much to Boas and Malinowski. Pareto, of course, made important contributions to sociology as well as to economics, while the influence of Marx extends across the fields of economics, sociology, political science, and history.

This new encyclopedia contains such a wealth of valuable contributions that it may seem rather ungracious to enter any reservations. I must, however, register a few.

Among the topics that might well have received more attention, I will mention only environmental pollution and poverty. The first is touched on only briefly in articles relating to water resources and the problems of cities. The single article on poverty as such, "Poverty" (Vol. 12), is by the distinguished political and social historian, E. J. Hobsbawm (London). He deals with the history and measurement of poverty—the question of how to abolish it being outside the scope of his assignment. Both of these areas present urgent problems with which social scientists are already deeply involved, and there can hardly be any dearth of qualified contributors.

With respect to agriculture, one would naturally expect a lesser concern with its problems today than in 1930-35. This, of course, reflects the steady decline in the farm population of the industrialized countries and in the relative contribution of agriculture to the national income. On balance, however, my judgment is that the allotment of space to the problems of agriculture is about minimal and that the potential of AAEA economists to make significant contributions could have been more fully exploited. It is also a matter of some regret that no members of the Editorial Advisory Board are identifiable as agricultural economists. Though some readers of this Journal may be horrified at the suggestion, I think that an encyclopedia of agricultural economics and rural sociology, comparable in quality to the one under review, could be of very great value.

In the preparation of this review, I made some compilations of contributors with the object of obtaining some perspective on geographic distribution, academic affiliation, and other characteristics. It was not possible to do this in great detail or with complete accuracy, but I think there is enough evidence for a few broad generalizations. These refer to the whole range of contributions, not just those in economics.

The present encyclopedia is labeled "international," and this designation is justified. Over 320 contributors, approximately 20 percent of the total, are from outside of the United States. However, these are highly concentrated. About 130 are from the United Kingdom, over 50 from France, over 40 from Germany, and around 50 from other Western European countries. Altogether, these represent about 80 percent of the total number of foreign contributors. Those from the U.K. are dominated by Oxford, Cambridge, and the University of London (about half from this source are attributable to the School of Economics and Political Science); while in France, the University of Paris stands out. Other countries with a fair number of contributors are Israel, Australia-New Zealand, and Canada, although there are fewer from Canada than I would have expected. Contributions from South America, Asia, and Africa are disappointingly small.

From within the United States, contributors total close to 1,200, somewhat more than 1,000 from the colleges and universities. Of the latter, the East accounts for approximately 47 percent; the Midwest, 28 percent; the Far West, 18 percent; the South and Southwest combined, 7 percent.

Certain schools tend to carry a heavy weight. In the East, the combined contributions of Harvard, Yale, Princeton, Pennsylvania, Cornell, Johns Hopkins, MIT, Columbia, New York University, and City University of New York account for over two-thirds of the total. Columbia leads this group with over 70 contributors. In the Midwest, Chicago, Michigan, Illinois, Northwestern, Minnesota, Wisconsin, and Indiana account for nearly three-fourths of the total. Chicago tops the list, both regionally and nationally, with about 80 contributors. The California schools dominate the Far West. The University of California (including Berkeley, Los Angeles, and other locations) and Stanford together account for over 70 percent of the total, the Berkeley campus leading with about 60 contributors. In the South and Southwest, North Carolina, Duke, Vanderbilt, Virginia, and Texas account for over half of the total.

One great difficulty in reviewing an encyclopedia is that the further one reads, the greater is the urge to change the emphasis and organization, even to the point of rewriting it completely. Another is the everpresent temptation to go poking into areas well beyond one's own discipline. However, as economists are notoriously overspecialized, this is probably all to the good. For a few interesting side trips, I recommend "Judaism" (Vol. 9), by Jacob Katz (The Hebrew University); "Existential Psychology" (Vol. 13), by Rollo May; "Minorities" (Vol. 10), by Arnold M. Rose; and "Civil Disobedience" (Vol. 2), by Christian Bay (University of Alberta). For a good scare, read "Nuclear War" (Vol. 11), by Herman Kahn, the controversial expert in this field. Fortunately, deadlines force one to stop some place and this is it.

Though I have entered a few caveats, these are minor in relation to the great merits of this encyclopedia as a whole. In my opinion, it is clearly superior to that published in the thirties. Although the earlier version was the work of a talented and formidable array of scholars, it leaned in the direction of short and relatively nontechnical articles designed to have a rather wide popular appeal. However admirable the objective, this approach tends to suffer from the fact that such articles often lack enough substance to attract the specialist, while at the same time they are likely to be too technical or colorless to held the interest of the general reader.

This encyclopedia is by social scientists and for them. The generally high quality of the articles and the stature of the authors should ensure wide use by both established professionals and graduate students. Of course, as with all encyclopedias, there is bound to be some lag between much that is written and the emergence of new ideas and the march of events. With respect to economic theory, the 1930-35 encyclopedia came out a little too soon to incorporate the ideas of such people as Chamberlin, Joan Robinson, Hicks, Harrod, Myrdal, and the later work of Keynes. The contributions of these and others have recently been placed in perspective by Shackle in his *Years of High Theory* [6]. On balance, the present encyclopedia is more contemporary with respect to ideas, methodology, and recent events than was its predecessor. Taken as a whole, the *International Encyclopedia of the Social Sciences* is an intellectual achievement of the first magnitude and deserves to be called a "Mightie Werke."

Some Implications of the EEC's Agricultural Price Policy*

DONALD J. EPP

This article indicates elements of the Common Agricultural Policy of the European Economic Community that may result in substantial changes in the future. Regional price indexes are developed for several grain and livestock commodities and projected to 1970 and 1975. By combining these projections with the results of an EEC survey of family farm incomes, this article shows that the projected price changes will favor the farmers with the highest incomes. Also, the operation of the Agricultural Fund causes a transfer of foreign exchange from member countries with agricultural net import balances to member countries with agricultural net export balances. Raising the internal prices of imported and exported commodities in order to establish a common price for the EEC has further increased the foreign exchange transfers.

INTERNATIONAL economic headlines have shifted from the arduous deliberations of the Kennedy Round of tariff negotiations and its accompanying drama of creating an agricultural policy for the EEC to the problems facing the United States and its balance of payments. This change of events might lead one to assume that the EEC has established a firm policy with respect to agricultural prices. It is the purpose of this paper to investigate the validity of such an assumption by raising the question: Have the initial steps in establishing an EEC policy activated forces that will ultimately lead to substantial revisions in EEC policy? If the answer is affirmative, it is prudent that we understand the working of these forces so as to anticipate the nature of future changes.

The hypothesis in this paper is that present EEC agricultural price policies will result in further disparities of income between large and small farms, and since the proportion of large and small farms is not uniform throughout the Community, this will hurt the foreign exchange position of some member countries and lead to economic and social problems within these countries.

A Study of Regional Prices

This study of the Common Agricultural Policy of the EEC emphasized three points: the impact of policy on prices received by producers, con-

sideration of regions that are reasonably homogeneous types of farming areas, and projection of the impact on prices to 1970 and 1975. Since the influence of any particular commodity price is likely to be affected by differences in enterprise combinations, the three large countries of the EEC were divided into regions that reflect general differences in commodities produced or types of farm organization. The eighteen agricultural regions of the EEC used in this study are shown in Figure 1. Projecting prices to 1970 and 1975 was not intended to prophesy, but rather, by extending the results of current policy forces under realistic assumptions about market conditions, to amplify any inconsistencies or potential conflicts.

The data come mainly from published reports of producer prices. Occasionally, needed information was obtained from unpublished sources, or was calculated from market prices with the use of marketing margins supplied by government and university researchers. For commodities that include several quality grades with different prices, such as beef and veal, the amount of each grade marketed was used as a weight for determining the weighted average price. In such cases, the resulting price estimates better reflect the returns to the farmer than do the unadjusted prices.[1]

The study of prices proceeded in three steps. First, the prices for a three year period centered on 1960 were analyzed to obtain the relationships between regions prior to the introduction of the EEC policies. Second, regional prices were projected to 1970, utilizing the price policies and price levels determined by the EEC for the unified market. And third, the price projections were extended to 1975 under the alternative assumptions (1) that nominal prices will remain at 1963–65 levels or (2) that policy-determined prices will increase at about the average rate of increase in nonagricultural prices.

In the second and third stages, the specific projection procedures varied for different groups of commodities, depending on the policy provisions affecting them. For grains, the 1970 intervention price of the Common Agricultural Policy provided the base from which producer prices were projected by maintaining the relationship between support prices and producer prices that existed in the base period. The Italian price projections were modified because of the special policies that apply to that country. All grain prices were further adjusted to reflect the transportation costs for moving grain between regions, thus providing an internally consistent price surface.

Because the production processes for hogs, broilers, and eggs are dependent on feed grains, the producer prices for these products were calculated from the grain prices estimated for each region and from producmore to the Fund than they receive, while the French, and possibly the Dutch, will receive more from the Fund for export restitutions than they contribute in import duties.

---

[1] See Epp [1, esp. Ch. 4 and the Appendixes] for a detailed description of the data and the price projection procedures.

While importing has always involved the loss of foreign exchange to purchase the commodities, any duty levied on the imports stayed within the country, being collected by the government. In essence, import duties transfer wealth from the purchasers of imported goods to the recipients of government expenditures. The basic principle does not change under the EEC policies, but because the taxing agent is the Agricultural Fund rather than the national government, the duty becomes an additional foreign exchange loss. This transfer of wealth still goes from the purchaser of imports to the recipient of Agricultural Fund expenditures, but the potential problem is that most of the recipients live in a different country than the majority of the contributors. Consumers in countries requiring large imports of agricultural products will contribute more to the Fund, while the producers of surplus commodities requiring support purchases and export restitutions will receive more from the Fund.

The analysis so far considers only the change of paying the duties to the Agricultural Fund rather than to national governments. But the prices currently established by the EEC regulations increase the transfer of funds from importing countries to surplus producing countries. Grain policies are an example. Since Italy is a large importer of feed grains, the increase in Italian feed grain prices results in higher duties and greater payments to the Agricultural Fund than would have been the case under Italy's former tariff rates. At the same time, prices will increase in France, resulting in the need for larger export subsidies to permit the surplus grain to compete on world markets. This means that the French exporters and farmers receive more from the Agricultural Fund than would have been the case under the former French tariffs.

An estimate of the income transfers from grain trade operations of the Agricultural Fund is shown in Table 2. Germany, Italy, Netherlands, and Belgium-Luxembourg are net contributors to the Fund while France is a net recipient. The purchasers of grains imported into the five net contributor countries (and, ultimately, the consumers of products made from the imported grains) paid almost 99 percent of the import levies received by the Fund. On the other hand, producers in France, the net recipient country, received almost 63 percent of the export restitutions paid from the Fund.

Table 2 also shows the magnitude of the import levies and export restitutions relative to the value of grain traded. The total import levies paid were 56 percent of the value of the imports and the export restitutions were almost 42 percent of the value of the exports. Thus, the Fund transactions concerning grain exports and imports are not only large in total

Table 2. Estimated values of grain imports and exports with import levies and export restitutions for the countries of the European Economic Community, 1967/68

Countries	Value of imports[a]	Import levies (paid to the Fund)	Value of exports[a]	Export restitution (received from the Fund)	Net position with the Fund (+net contributor) (−net recipient)
			dollars		
Germany	393,807,210	227,971,320	50,523,070	23,406,360	+204,564,960
Italy	435,868,060	239,324,420	54,136,800	25,263,840	+214,060,580
Netherlands	232,176,230	128,466,340	22,511,280	10,977,960	+117,488,380
Belgium-Luxembourg	119,296,040	68,136,570	12,938,540	6,041,670	+ 62,094,900
France	12,548,700	8,295,130	283,296,160	110,561,900	−102,266,770

[a] The value of exports and imports is calculated from reported volume of trade and the annual average price for each grain at Rotterdam. The volume of grain traded and the average prices used are found in European Economic Community [3].

value but are a large portion of the total receipts and costs of exporting and importing grains.

While this example is the most obvious, similar conclusions can be drawn from Germany's imports of livestock products and Dutch exports of dairy products. In essence, the financing of the Agricultural Fund causes a transfer of funds from net importing countries to net exporting countries, and establishing a common price level increases the magnitude of this transfer.

Implications

The most important implication of the preceding analysis for American policy is that the EEC policies are likely to shift and adjust to the pressures indicated. To assume that the results of the long and arduous negotiations will provide a rigid price and income policy for European agriculture is a mistake. While the basic direction of the EEC policies is unlikely to change, it is probable that the specific policy measures or price levels for certain commodities may be changed. Naturally, any change in the composition of the Community will necessitate adjustments and such an occasion may be used to correct some of the imbalances currently developing. If new members are admitted to the EEC, recognition of the difficulties in the present system may facilitate a clearer understanding of any policy changes that occur.

In order to assess the likelihood of alternative policies being adopted, we need to know more about the relative political strength of different groups in the new policy making organizations in Western Europe. The differences in the incidence of benefits and costs of the Common Agricultural Policy are apparent, but it is difficult to determine the impact of income disparities and transfer of income on future policy decisions. An analysis of the role of the various economic and political groups in form-

Projecting the Size Distribution of Agricultural Firms—An Application of a Markov Process with Non-Stationary Transition Probabilities*

M. C. HALLBERG

The first-order Markov chain model is frequently used to project the future size distribution of firms in a particular industry. This model, however, is based on the rather restrictive assumption that the transition probabilities remain constant over time. This assumption was found to be inappropriate in the case of plants manufacturing frozen milk products in Pennsylvania during the period 1944-1963 and, if adopted, could lead to erroneous results as some actual predictions indicated. This article suggests a method, based on multiple regression techniques, of replacing the constant transition probabilities with probabilities which are a function of various factors including structural characteristics in the industry. The results of this procedure compared quite favorably with those of the assumption of constant probabilities.

THE dynamic and stochastic nature of most economic phenomena has led several economists to postulate that the evolution of certain economic variables over time can be characterized as a stochastic process. The Markov chain model is frequently utilized as the stochastic model with which to predict the future time path of such variables. As a method of analyzing the *current* movement of a variable in order to predict its future movement, the Markov chain model can be extremely useful to social scientists in designing policy measures compatible with the *future* movement of the stochastic variable in question. Further, once the process of change is understood, one may then be in a position to suggest how the process must be altered in order to realize some specific target outcome.

One of the most demanding assumptions of the Markov chain model is that the probability of occurrence of a particular outcome in any one trial of the sequence does not change throughout the entire sequence—that is, the transition probabilities are assumed to be stationary. This means that once the process of change has been established, the same process of change will continue indefinitely.

Providing "all else remains equal," this may be a very realistic assumption. But when such phenomena as the size distribution of firms in an industry are studied, the stationarity assumption appears to be untenable in most cases. Changes in numerous exogenous variables—wage rates, factors

---

* Authorized for publication as paper number 3506 in the journal series of the Pennsylvania State University Agricultural Experiment Station. I am appreciative of the helpful comments and criticism received from George Brandow, Lee Day, Wayne Schutjer, and the anonymous referees on earlier versions of this paper.

M. C. HALLBERG *is assistant professor of agricultural economics at The Pennsylvania State University.*

affecting demand for the industry's product, technology, and legal requirements—are likely to result in non-stationary transition probabilities. Simply to argue, as is commonly done, that the results of the Markov chain model are what can be expected (in a probabilistic sense), assuming all exogenous variables remain the same, is neither helpful nor informative.

The purpose of this paper is twofold. First, a procedure is outlined that is designed to incorporate a non-stationarity assumption into the Markov chain model. This is done by replacing the stationary probabilities with probabilities that are a function of exogenous factors subject to change throughout the sequence of experiments. Second, the effect of this procedure is illustrated with the use of data on changes in the size distribution of plants manufacturing frozen milk products in Pennsylvania.

The Basic Model and Tests

A stochastic process may be described as a sequence of experiments in which the outcome on each individual experiment in the sequence depends on some probability, p, or chance event. If the probability of the outcome of a given trial, say the t^{th}, depends only on the outcome of the immediately preceding trial, if this probability is the same for each trial in the sequence, and if the set of possible outcomes is finite, the process is known as a first-order Markov chain. For systems thus characterized, one may deduce the probability, p, that the system will be in a given state at a given time, t, from a knowledge of its state at an earlier time, t-1 [see 5, 8].

Consistent with our definition of a Markov chain, let:

s_i = the i^{th} state of a set of n states, $i = 1, 2, \cdots, n$,

$P = [p_{ijt}]$ = the $n \times n$ matrix of transition probabilities, where p_{ijt} represents the probability that outcome s_j will result from the t^{th} experiment given that outcome s_i occurred on the $(t-1)^{th}$ experiment, $t = 1, 2, \cdots, T$,

$X_0 = [x_{0i}]$ = the initial starting state vector or the initial configuration of individuals in the n states, where x_{0i} represents the number of individuals in state s_i during time period $t = 0$,

$X_t = [x_{ti}]$ = t^{th} configuration vector, and

m_{ijt} = number of individuals in s_i during period $t-1$ who moved to s_j in period t.

In addition, we impose two constraints on the elements of the matrix P:

$$p_{ijt} \geq 0 \quad \text{for all } i, j, t, \text{ and} \tag{1}$$

$$\sum_{j=1}^{n} p_{ijt} = 1 \quad \text{for all } i \text{ and } t. \tag{2}$$

Given P and X_0, the future path of the stochastic process is given by:

$$X_t = X_0 P^t. \tag{3}$$

If P is a stochastic matrix satisfying (1) and (2), there exists an $n\times n$ matrix P_e to which P^t will converge as $t\rightarrow\infty$ consisting of n rows which are exactly alike [5]. Hence, X_0P_e gives the equilibrium configuration, X_n, of the stochastic process.

Anderson and Goodman [1] have shown that the maximum likelihood estimates of the transition probabilities based on actual movements of individuals between states are:

$$\hat{p}_{ijt} = m_{ijt} \Big/ \sum_{j=1}^{n} m_{ijt}. \tag{4}$$

If information is available for several time periods—i.e., if m_{ijt} are available for each of the $t=1, 2, \cdots, T$ time periods—Anderson and Goodman [1] have also shown that the maximum likelihood estimates of the stationary transition probabilities are:

$$\hat{p}_{ij} = \sum_{t=1}^{T} m_{ijt} \Big/ \sum_{j=1}^{n}\sum_{t=1}^{T} m_{ijt}. \tag{5}$$

Given the estimates, $\hat{p}_{ij}$, it is possible to test the null hypothesis that the true transition probabilities are stationary. The test statistic is [1]:

$$-2\log\lambda = 2\left(\sum_{i}^{n}\sum_{j}^{n}\sum_{t=1}^{T} m_{ijt}\log\hat{p}_{ijt} - \sum_{i}^{n}\sum_{j}^{n}\sum_{t=1}^{T} m_{ijt}\log\hat{p}_{ij}\right) \tag{6}$$

and is distributed as χ_ν^2, with $\nu=(T-1)\cdot(n-1)\cdot n$ degrees of freedom.[1]

Derivation of Non-Stationary Transition Probabilities

When the test for stationarity indicates that the null hypothesis cannot be accepted, the model must be modified to incorporate the alternative hypothesis. The alternative hypothesis with which we must contend is: the transition probabilities are not constant over time. *A priori* information may reveal some indication as to the nature of the functional relation between the transition probabilities and certain exogenous factors. For example, the transition probabilities may fluctuate cyclically. They may change with fluctuations in profit rates, inventory accumulations, demand, advertising, interest rates, etc. Or, in the case of a sociological analysis, they may change with fluctuations in various non-economic factors.

Telser [11, 12, 13] has utilized the hypothesis of non-stationarity in two analyses dealing with the demand for branded goods. In Telser's work, however, the transition probabilities, as well as the effect of the exogenous variables on the transition probabilities, were estimated indirectly because a time series of actual transition probabilities was unavailable.

In our case, we assume the existence of a time series of transition probability matrices and desire a statistical relationship between the p_{ijt}'s and a set of exogenous factors z_{kt}, $k=1, 2, \cdots, K$. We propose fitting a least squares regression equation of the form,

---

[1] For large values of ν, $\{T_\alpha+\sqrt{2\nu-1}\}/2$ gives the approximate value of the tabulated χ^2 where T_α is the α point of the culmative normal distribution [see 7 p. 428].

$$\hat{p}_{ijt} = \hat{\alpha}_{ij} + \sum_{k=1}^{K} \hat{\beta}_{ijk} z_k,$$

for each of the n^2 cells of the transition probability matrix. For resaons that will become obvious later, we will include all data pertaining to any one row of the P matrix into a single regression equation so as to estimate the $n+nK$ parameters for that one row simultaneously.

Accordingly, we assume the sample observations are generated by the linear regression model:

(7) $P=QB+U$ for each i (i.e., row of the transition matrix)

with $E(U)=\phi$ and $E(UU')=\sigma^2 I$ where the $Tn\times 1$ vector of observations on the dependent variable is

$$P = \left|\begin{array}{c} P_1 \\ \cdot \\ \cdot \\ \cdot \\ P_j \\ \cdot \\ \cdot \\ \cdot \\ P_n \end{array}\right| \qquad \underset{T\times 1}{P_j} = \left|\begin{array}{c} p_{ij1} \\ \cdot \\ \cdot \\ \cdot \\ p_{ijt} \\ \cdot \\ \cdot \\ \cdot \\ p_{ijT} \end{array}\right|;$$

the $(Tn)\times(n+K)$ matrix of observations on the $n+nK$ independent variables is

$$Q = \begin{bmatrix} Q_0 & & & \phi \\ & Q_0 & & \\ & & \ddots & \\ \phi & & & Q_0 \end{bmatrix}, \qquad \underset{T\times(1+K)}{Q_0} = [Z_0 Z_1 \cdots Z_k \cdots Z_K]$$

where Z_0 is a $T\times 1$ vector with all elements unity and Z_k is a $T\times 1$ vector of observations on the k^{th} exogenous variable; the $(n+nK)\times 1$ vector of coefficients is

$$B = \begin{bmatrix} B_1 \\ \cdot \\ \cdot \\ \cdot \\ B_j \\ \cdot \\ \cdot \\ \cdot \\ B_n \end{bmatrix} \qquad B_j = \begin{bmatrix} \alpha_{ij} \\ \beta_{ij1} \\ \cdot \\ \cdot \\ \cdot \\ \beta_{ijk} \\ \cdot \\ \cdot \\ \cdot \\ \beta_{ijK} \end{bmatrix} = \begin{bmatrix} \alpha_{ij} \\ \hline B_{ij} \end{bmatrix}$$

where α_{ij} is the intercept and β_{ijk} the slope coefficient on the k^{th} independent variable; and U is a $Tn \times 1$ vector of random errors.

This formulation is based on the assumption that the same set of exogenous factors can be used to explain the variation in each p_{ij} in any row, i, of the transition probability matrix.[2] This seems a reasonable assumption since we are attempting to explain why elements in the i^{th} state move to another state or stay in the same state. The behavior of elements in other states may be governed by a different set of exogenous factors.

The least squares estimate of B is

$$\hat{B} = (Q'Q)^{-1}Q'P. \tag{8}$$

But from the construction of Q we note that

$$\hat{B}_j = (Q_0'Q_0')^{-1}Q_0'P_j \quad \text{for all } j, \tag{9}$$

which contains the estimated intercept and slope coefficients for the j^{th} element in the i^{th} row of the transition probability matrix.

Substituting the least squares estimate of B_j into the equation used to predict p_{ijt}, we have:

$$\hat{p}_{ijt} = Q^*\hat{B}_j. \tag{10}$$

This can be written equivalently in deviation form as:

$$\begin{aligned} \hat{p}_{ijt} &= \hat{\alpha}_{ij} + Z^*\hat{B}_{ij} = (\bar{p}_{ij.} - \bar{Z}\hat{B}_{ij}) + Z^*\hat{B}_{ij} \\ &= \bar{p}_{ij.} + (Z^* - \bar{Z})(z'z)^{-1}z'p_j, \end{aligned} \tag{10'}$$

where the starred vectors contain the observed values of the Z_k in time period t, $\bar{Z}$ is a vector of means of the Z_k over T time periods, z is a $T \times K$ matrix of the Z_k in deviation form, and p_j is a $T \times 1$ vector of transition probabilities in deviation form.

Since $p_{i.t} = 1$ for each i and t,

$$\sum_{j=1}^{n} \bar{p}_{ij.} = 1 \quad \text{for each } i.^3 \tag{11}$$

But $p_{i.t} = 1$ and equation (11) together imply that

$$\sum_{j=1}^{n} \hat{B}_{ij} = \sum_{j=1}^{n} (z'z)^{-1}z'p_j = (z'z)^{-1}z' \sum_{j=1}^{n} p_j = \phi, \tag{12}$$

---

[2] This formulation also depends on the rather tenuous assumption that the variances of the error terms of all cells in a given row are equal. A more realistic assumption might be that $\sigma_{ij} = f(i-j)$. If this form of heteroskedasticity is assumed, it can be demonstrated that the results obtained in equations (11) to (13) in this section remain unchanged. Only the variances of our least squares estimates will be affected.

[3] The dot notation is used here and elsewhere in this paper to indicate summation over the entire range of the subscript replaced by a dot. As usual a bar placed over the variable indicates a mean value.

where ϕ is the $K\times 1$ null vector. Therefore,

$$\sum_{j=1}^{n} \hat{p}_{ijt} = \sum_{j=1}^{n} \bar{p}_{ij.} = \sum_{j=1}^{n} \hat{\alpha}_{ij} = 1 \tag{13}$$

This result is important. It means that the constraint on the transition probabilities given by equation (2) is satisfied. Further, the information obtained from equations (12) and (13) may be useful in an application of restricted least squares.

The $K+1$ restrictions from equations (12) and (13) are equivalent to imposing the restriction

$$\begin{bmatrix} 1 \\ \phi \end{bmatrix} = RB \tag{14}$$

on model (7) where R is the $(K+1)\times(n+nK)$ matrix consisting of n identity matrices of order $(K+1)$.

Providing all parameters of the n equations in a given row are to be estimated, the $K+1$ independent restrictions imposed by (14) are satisfied, and we can estimate the coefficient vector, B, of (7) by classical least squares.

If some of the parameters of these n equations are assumed *a priori* to be zero, it appears desirable to apply the restricted least squares technique as outlined in Goldberger [2]. Specifically, on the basis of equations (11) to (13), it would seem reasonable to impose restrictions of the type specified in equation (14). That is, the estimated non-zero intercepts should sum to unity and the estimated non-zero slope coefficients on a given exogenous variable should sum to zero in any one row of the transition probability matrix.

Once all parameters have been estimated, the individual transition probabilities in time period t can be estimated, given values of the exogenous variables in the same time period.

One problem yet remaining is that the estimated transition probabilities, while always satisfying equation (2), will not necessarily lie within the range specified by equation (1). To avoid this difficulty, the following rule is suggested: First, if in any time period, t, $\hat{p}_{ijt}$ becomes negative (greater than unity), set $\hat{p}_{ijt}$ equal to zero (unity). Secondly, divide all remaining positive $\hat{p}_{ijt}$ in row i in time period t by their sum (set all other $\hat{p}_{ijt}$ equal to zero). This rule is admittedly arbitrary but is believed reasonable and, in the absence of a satisfactory alternative, was used in the analysis which follows.

The newly defined transition probabilities are to be substituted for the constant probabilities in the Markov chain model. Now, however, a study of the properties of the process over time must involve the use of simulation techniques, since there is no general solution to the difference equation

$$X_t = X_{t-1}\hat{P} \tag{15}$$

(where $\hat{P}$ is the $n \times n$ matrix with elements in the form of equation (10) above) comparable to that of equation (3) unless, of course, we have at our disposal "equilibrium" values for the exogenous variables.

Implications of Non-Stationary Transition Probabilities

Sales volume data over a 20-year period, from 1944 to 1963, for Pennsylvania plants manufacturing frozen milk products were obtained from the Crop Reporting Service, Pennsylvania Department of Agriculture.[4] During this period, the movement of 884 plants (all of which were in operation for at least one year during the 20-year period, but not all 884 during the same year) from one size category (state) to another was observed. For our purposes, five size categories were established:

s_1 · · · plants producing 50,000 gallons of output or less annually,
s_2 · · · plants producing between 50,001 and 300,000 gallons of output annually,
s_3 · · · plants producing between 300,001 and 1,000,000 gallons of output annually,
s_4 · · · plants producing more than 1,000,000 gallons of output annually, and
s_5 · · · plants producing no output during the given year.

The fifth state was utilized to represent a pool from which entrants may come and to which exants may go. Thus, the entire 884 firms will be accounted for in each of the time periods under consideration even though some may go out of business. Transition probabilities were estimated for each of the 19 time periods according to equation (4) and $\hat{p}_{ij}$ were estimated according to equation (5). The matrix $[\hat{p}_{ij}]$ is:

$$\hat{P} = \begin{bmatrix} .76816 & .04764 & .00119 & .00040 & .18261 \\ .07612 & .86597 & .02212 & .00066 & .03513 \\ .01786 & .06786 & .83928 & .04643 & .02857 \\ .00369 & .00369 & .01845 & .96310 & .01107 \\ .03356 & .00484 & .00041 & .00041 & .96078 \end{bmatrix} \tag{16}$$

The computed X^2 for testing the hypothesis that the transition probabilities are constant is 749.14 with 360 degrees of freedom. Hence, we fail to accept the hypothesis that the transition probabilities are constant over the 20-year period.

It is instructive at this point to examine the results of using inappropriate transition probabilities. First, I used the $\hat{p}_{ij}$ given in (16) and the configuration of plants observed in 1944 as X_0. Second, I used the $\hat{p}_{ij}$ observed for the period 1954–1955 and the configuration of plants observed in 1955 as X_0. Third, I used the $\hat{p}_{ij}$ observed for 1949–50 and the configuration of plants observed in 1950 as X_0. Finally, I used the maximum likelihood estimates, $\hat{p}_{ij}$, over the period 1949–54 and the configuration of plants observed in 1949 as X_0.[5] In each case, I employed the Markov chain model with the stationarity assumption to simulate the future configuration of plants over the relevant time periods ending with 1963. The results are depicted in Figure 1. The equilibrium configuration for the four cases are respectively:

---

[4] For further discussion and analysis of these data see [6].

$$\begin{aligned} &1944\text{–}1963 - X_e = [120 \quad 75 \quad 16 \quad 30 \quad 643] \\ &1950 \qquad\quad\; - X_e = [236 \quad 124 \quad 47 \quad 0 \quad 477] \\ &1955 \qquad\quad\; - X_e = [117 \quad 57 \quad 10 \quad 0 \quad 700] \\ &1949\text{–}1954 - X_e = [155 \quad 102 \quad 36 \quad 45 \quad 546] \end{aligned}$$

None of these four cases yields reasonably good estimates of the 1963 structure, as can be seen in Figure 1.

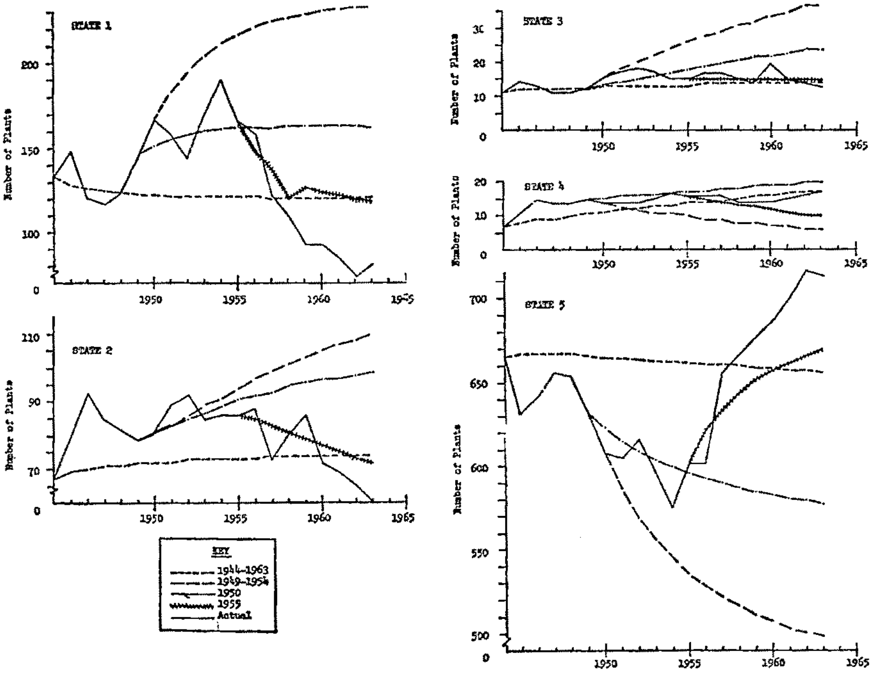

Figure 1. **Markov chain predictions with stationary transition probabilities**

The fourth case considered deserves special comment. Assume for the moment that the present year is 1954 and we have only the data for 1949 to 1954. Upon calculating the transition probabilities and applying the χ^2

---

[5] In this latter case, I accepted the null hypothesis that the transition probabilities were stationary according to the likelihood ratio criterion given in equation (6).

test, we find them to be stationary, and we proceed to make judgments on the basis of Markov chain predictions using this information. By 1957 we would be extremely embarrassed. The embarrassment would be due, of course, to the fact that changes in income, consumption, and costs after 1955 had a substantial impact on market structure in the industry, even though the χ^2 test suggested that our transition probabilities were stationary. Had we known the effect of rising incomes, demand, costs, etc., on market structure in the frozen milk products industry, we might have been able to predict the 1957 and subsequent years' structure more precisely.

In an attempt to improve upon the predictive and explanatory power of the Markov chain model, the technique outlined in the preceding section was applied to these data. In this analysis, the following exogenous variables were utilized on the hypothesis that factors influencing the demand for and costs of producing manufactured dairy products would explain a major portion of the variation in the observed transition probabilities:

z_{1t} = Index of hourly earnings of workers engaged in food manufacturing industries in the U. S., deflated [15],
z_{2t} = Population in Pennsylvania, [10, 16],
z_{3t} = Per capita income in Pennsylvania, deflated [10, 16],
z_{4t} = Price per hundredweight received by Pennsylvania farmers for all milk, deflated [14], and
z_{5t} = Index of retail price of all dairy products in the U. S., deflated [14].

We have previously specified that the transition probabilities should fall within the closed interval from zero to unity, and hence, we would like to impose the restriction that $0 \leq \hat{p}_{ijt} \leq 1$ for all feasible values of the exogenous variables. This condition would have been met had we taken a reciprocal transformation of all exogenous variables and restricted all the α's to the closed interval from zero to unity.[6] Since it is not possible to impose such a restriction when using least squares, and since initial graphical work suggested that a logarithmic transformation might well be superior to a reciprocal transformation, all exogenous variables were expressed in logarithms prior to an application of model (7) to these data.

Prior regression analysis indicated that lagged values of the exogenous variables did not produce significant results and that some of the regression coefficients were not significantly different from zero at the ten percent level. If the latter were true for a given equation, that equation was reestimated under the following restrictions:

(1) the omitted coefficients were zero,

(2) $\sum_{j=1}^{5} \hat{\alpha}_{ij} = 1$ for all $i = 1, 2, \cdots, 5$ (including the zero coefficients),

---

[6] This could be done using quadratic programming; however, information pertaining to the reliability of estimates would be unavailable.

and

(3) $\sum_{j=1}^{5} \beta_{ijk} = 0$ for all i and all k (again including the zero coefficients).

Statistics from the resulting regression analysis are as follows:

Row 1:

$\hat{\alpha}_{11} = -7.0361$ (1.2228)

$\hat{\alpha}_{12} = 2.8341$ (1.2019)

$\hat{\alpha}_{15} = 5.2020$ (1.2228)

$\hat{\beta}_{112} = -1.9414$ (0.3039)

$\hat{\beta}_{152} = 1.9414$ (0.3039)

$\hat{\beta}_{124} = 0.5666$ (0.2539)

$\hat{\beta}_{154} = -0.5666$ (0.2539)

$\hat{\beta}_{125} = -1.5887$ (0.6677)

$\hat{\beta}_{155} = 1.5887$ (0.6677)

$R^2 = 0.9935$

Row 2:

$\hat{\alpha}_{21} = -0.3224$ (0.5655)

$\hat{\alpha}_{23} = 1.1350$ (0.4257)

$\hat{\alpha}_{25} = 0.1874$ (0.5655)

$\hat{\beta}_{222} = 0.2765$ (0.1058)

$\hat{\beta}_{232} = -0.2765$ (0.1058)

$\hat{\beta}_{215} = 0.1976$ (0.2811)

$\hat{\beta}_{225} = -0.1216$ (0.2117)

$\hat{\beta}_{255} = -0.0760$ (0.2812)

$R^2 = 0.9979$

Row 3:

$\hat{\alpha}_{33} = -9.7418$ (1.2492)

$\hat{\alpha}_{34} = 10.7418$ (1.2492)

$\hat{\beta}_{331} = -1.6842$ (0.2889)

$\hat{\beta}_{341} = 1.6842$ (0.2889)

$\hat{\beta}_{332} = 3.5671$ (0.4324)

$\hat{\beta}_{342} = -3.5671$ (0.4324)

$\hat{\beta}_{323} = 0.0240$ (0.0020)

$\hat{\beta}_{333} = -0.0240$ (0.0020)

$R^2 = 0.8882$

Row 4:

$\hat{\alpha}_{41} = -0.0321$ (0.0700)

$\hat{\alpha}_{43} = -0.1794$ (0.0700)

$\hat{\alpha}_{44} = 1.3006$ (0.0700)

$\hat{\alpha}_{45} = -0.0891$ (0.0700)

$\hat{\beta}_{414} = 0.2443$ (0.0970)

$\hat{\beta}_{434} = 0.2751$ (0.0970)

$\hat{\beta}_{444} = -0.4670$ (0.0970)

$\hat{\beta}_{454} = -0.0524$ (0.0970)

$R^2 = 0.9986$

Row 5:

$\hat{\alpha}_{51} = 3.6149$ (0.2082)

$\hat{\alpha}_{52} = 0.2208$ (0.0324)

$\hat{\beta}_{552} = 0.7602$ (0.0705)

$\hat{\beta}_{513} = -0.4078$ (0.0223)

$$\begin{array}{llll}
\hat{\alpha}_{55} = & -\,2.8357\ (0.2082) & \hat{\beta}_{553} = & 0.4078\ (0.0223) \\
\hat{\beta}_{511} = & -\,0.4625\ (0.0271) & \hat{\beta}_{514} = & 0.8000\ (0.0596) \\
\hat{\beta}_{521} = & -\,0.0988\ (0.0149) & \hat{\beta}_{554} = & -\,0.8000\ (0.0596) \\
\hat{\beta}_{551} = & 0.5613\ (0.0271) & \hat{\beta}_{515} = & 1.1982\ (0.1037) \\
\hat{\beta}_{512} = & -\,0.7602\ (0.0705) & \hat{\beta}_{555} = & -\,1.1982\ (0.1037) \\
 & & R^2 = & 0.9902.
\end{array}$$

Since all exogenous variables were expressed in natural logarithms, the rate of increase (or rate of decrease if the relevant regression coefficient is negative) of the dependent variable declines as a given exogenous variable increases. That is, at a given level of z_k:

$$\frac{\partial p_{ij}}{\partial z_k} = \lambda \hat{\beta}_{ijk} z_k^{-1}$$

where $\lambda = \log_{10} e = .4343$.

Several interesting features are suggested by the regression estimates. First is the effect of changes in price received by farmers (and hence the cost of milk to processors) on the movement of firms from one state to another. As this variable increases, the probability of small firms becoming larger increases slightly ($\hat{\beta}_{124} > 0$). The indication is that when the farm price of milk increases, management of some of the already established firms in the frozen milk products industry in Pennsylvania see a need to expand the size of their business. Management of the large firms, on the other hand, apparently becomes more reluctant to expand their operations as the farm price of milk increases ($\hat{\beta}_{414}$, $\hat{\beta}_{434} > 0$ while $\beta_{444} < 0$).

When we concentrate on those factors associated with a shift in demand, we see that the probability of new firms entering the industry declines as per capita income increases ($\hat{\beta}_{513} < 0$) and as population increases ($\hat{\beta}_{512} < 0$). Furthermore, an increase in population appears to be associated with a decrease in the probability of established firms becoming larger ($\hat{\beta}_{232}$, $\hat{\beta}_{342} < 0$).

Much more work needs to be done in order to determine the appropriate combination of explanatory variables in the analysis illustrated here. We have included both profit and cost considerations but not technological considerations. We confined our analysis to the short-run, ignoring such long-run considerations as historical profit levels. Finally, due to data limitations, some of the variables used were not entirely satisfactory for explaining variations in the behavior of Pennsylvania firms.

Despite these limitations, the estimated relations presented above were used to simulate the number and size distribution of plants between 1945 and 1963. This was done in a recursive fashion according to equation (15), where the output generated for one period was used as input for the next.

To start the procedure, the initial configuration of plants existing in 1944 was used.

The results of this simulation run are plotted in Figure 2. Considering the entire time series, the configurations simulated under the assumption of non-stationary transition probabilities appear much more realistic than those simulated under the assumption of stationary probabilities. As may be expected, the model in general generated its poorest information for the war and immediate post-war years.

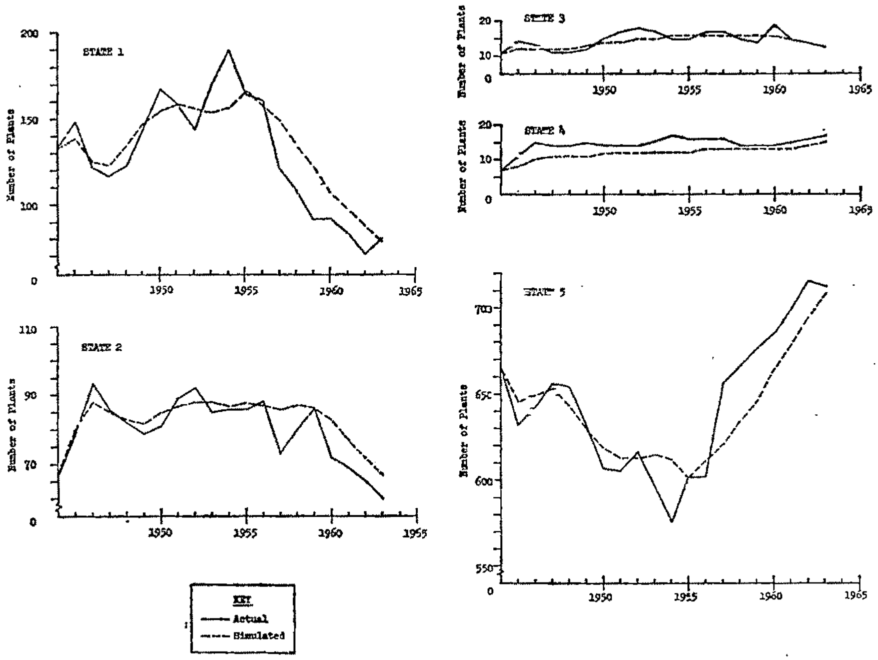

Figure 2. Predictions from the Markov chain model with non-stationary transition probabilities

Another interesting result from the simulation run is the frequency with which the model generated transition probabilities which were either negative or greater than one. In only three of the 19 years did this occur, and in each case element $\hat{p}_{55}$ exceeded one (while element $\hat{p}_{51}$ was negative). The actual numbers generated were 1.001, 1.0058 and 1.0034, respectively. Furthermore, these three years were the last in our series. Although it seems peculiar that this phenomenon occurred in each of the last three years of our series, the magnitude of these numbers hardly leads one to conclude that the model is exploding.

Conclusions

The Markov chain model has been used in several economic analyses with limited regard for implications of the erroneous assumption that the transition probabilities are stationary. Some implications of this assumption were discussed and a modification of the Markov chain model to incorporate a non-stationarity assumption was suggested.

An application of the technique produced results that were considerably more desirable from a predictive standpoint than results obtained from the traditional Markov chain model. This was true in spite of the fact that in one instance the likelihood ratio test indicated stationary transition probabilities.

The empirical analysis in this paper was intended to be illustrative rather than final. Additional work needs to be done to determine the appropriate structural system from which the transition probabilities are generated, as well as the appropriate form of the structural equations. For this purpose, a thorough understanding of the factors responsible for the growth process of firms is essential (including behavioral and financial factors). Such knowledge, unfortunately, does not currently exist.

Once the system from which transition probabilities are generated is known, one would then be in a position to (a) determine the short- or long-run effects of changes in relevant variables necessary to produce the desired short- or long-run effects, and/or (b) obtain other information from the Markov chain model such as attrition rates, mobility indices, etc. [see 3 and 4].

The Welfare Cost of Alternative Methods of Protecting Raw Wool in the United States

Rachel Dardis and Janet Dennisson

Partial equilibrium analysis was employed to estimate the gain or loss accruing to the United States in adopting alternative methods of protection for raw wool. The cost estimates, which were calculated for 1963, indicated that the economy had gained from the adoption of a partial deficiency payments system in 1954. However, further gains could have been made if the raw wool and compensatory wool products tariffs had been replaced by increased deficiency payments. The cost to the economy of maintaining the present system of protection for raw wool ranged from $13 to $26 million, depending on the particular elasticity of demand used. The results demonstrate the necessity for considering interaction between intermediate and final goods in evaluating alternative methods of protection.

THE United States, as a deficit producer of raw wool, must rely on imports to meet her requirements. Raw wool imports, however, pose a strong threat to the U. S. wool sector, both in terms of quality and price. As a result, governmental protection of the U. S. wool sector is necessary to enable it to compete with imported wool.

Various methods of protection have been in operation in the United States in the postwar period—price support programs, incentive programs, and tariffs on raw wool. The present system of protection for raw wool in the United States is a combination of tariffs and deficiency payments. It was instituted in 1954 with the passage of the National Wool Act, which introduced a new method of support for wool growers [10]. Under this method, raw wool is sold in the open market and cash subsidies (deficiency payments) are granted to growers to compensate for the difference between the open market price and an administratively determined producer price. Prior to 1954, non-recourse loan price support programs had been in effect and had resulted in the accumulation of considerable stocks of raw wool by the Commodity Credit Corporation in 1952 and 1953 [13, p. 36]. The 1954 Act eliminated the cost of acquiring and storing wool and reduced the price of raw wool to the wool textile industry.

The existence of a tariff on imported raw wool, however, means that the textile industry is still unable to purchase raw wool at world market prices. The tariff on raw wool amounts to 25½ cents per pound and raises the open market price of raw wool by this amount.[1] In addition, a compensatory

---

[1] During the recent Kennedy round consideration was given to the removal of the raw wool tariff, but no agreement could be reached in time [11, p. 9].

Rachel Dardis *is associate professor of textiles and clothing at Cornell University. Janet Dennisson was formerly research assistant in the Department of Textiles and Clothing, Cornell University.*

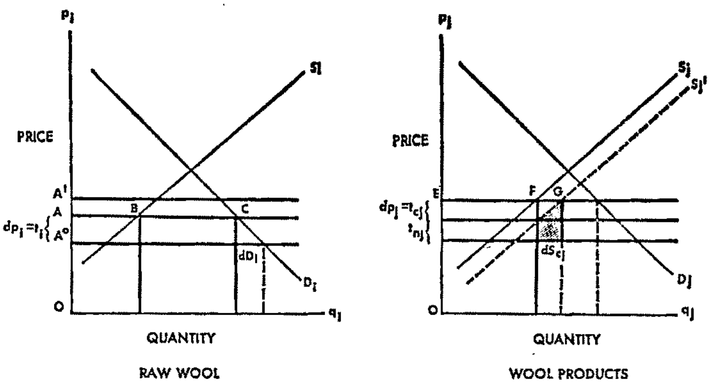
This expression can be further simplified if we remember that raw wool is an essential or limitational input in the production of wool textiles. Thus, the compensatory tariff is related to the raw wool tariff and the amount of raw wool required to produce one unit of output.[5] Under these circumstances,

$$t_{cj} = t_i(AC/EF), \quad \text{and}$$
$$\text{Gain} = t_{nj}dD_{cj} + \tfrac{1}{2}t_{cj}dD_{cj}.$$

This gain is represented in Figure 2 by the shaded area. It may also be considered the loss to the economy from continuing to employ the present system of protection for raw wool, a loss which could be removed with the adoption of a complete deficiency payments system for raw wool. It is interesting to note that the adoption of this new system would not interfere, in any way, with producers' surplus in either the raw wool or wool products sectors.

Case II: Removal of the raw wool tariff only (Figure 3)[6]

In this case, only the raw wool tariff is removed. It is replaced by increased deficiency payments of AA^0 per unit of production in the raw wool sector, resulting in a loss to the government of t_iAC, as in Case I.



RAW WOOL

WOOL PRODUCTS

Figure 3. Case II: Removal of the raw wool tariff only

---

[5] For example, if 2 pounds of raw wool are required to produce one pound of wool products, then a tariff change of $0.25 for raw wool requires a tariff change of $0.50 for wool products. The determination of the compensatory tariff for various wool products is, in fact, based on this principle.

[6] The fact that the compensatory and raw wool tariffs are related does not necessarily imply that both tariffs will be discontinued at the same time. The wool products manufacturer might, in fact, seek the removal of the raw wool tariff as a method of increasing protection of the wool products industry. Case II is also of interest in that it demonstrates that a tariff removal need not necessarily result in a welfare gain to the economy if the protected good is an input in an industry that is itself protected.

In the wool products sector, the removal of t_i has again resulted in the shift of S_j to S_j'. Unlike Case I, however, there is an increase in producers' surplus of $t_{cj}(EF+\frac{1}{2}dS_{cj})$, since the wool products price has not been reduced. The continuance of the compensatory tariff in this instance also means that there is no gain in consumers' surplus. There is, however, a loss in custom revenue of $(t_{cj}+t_{nj})dS_{cj}$, as domestic production responds to lower input prices. Combining the losses in both sectors and subtracting from them the gain in producers' surplus in the wool products sector, we obtain

$$\begin{aligned}\text{Cost} &= t_iAC + (t_{cj} + t_{nj})dS_{cj} - t_{cj}(EF + \tfrac{1}{2}dS_{cj})\\ &= t_iAC + t_{nj}dS_{cj} + \tfrac{1}{2}t_{cj}dS_{cj} - t_{cj}EF\\ &= t_{nj}dS_{cj} + \tfrac{1}{2}t_{cj}dS_{cj}, \text{ assuming}\\ t_{cj} &= t_i(AC/EF).\end{aligned}$$

The cost in this case reflects the cost to the economy when the compensatory tariff is retained in spite of the removal of the raw wool tariff. This cost arises from increased domestic production in response to lower input prices. The results of Case II differ from those of Case I in that a net loss rather than a net gain is endured by the economy. The only gainers in Case II are the producers of wool products, and their increase in welfare is purchased at the expense of the rest of the economy.

In this context, relative cost, or cost as a percentage of the change in producers' surplus in the wool products sector, is of interest. It may be expressed as follows:

$$\text{Relative Cost} = \frac{t_{nj}dS_{cj} + \frac{1}{2}t_{cj}dS_{cj}}{t_{cj}EF + \frac{1}{2}t_{cj}dS_{cj}} = \frac{t_{nj}dS_{cj} + \frac{1}{2}t_{cj}dS_{cj}}{t_{cj}S_j + \frac{1}{2}t_{cj}dS_{cj}}\,.$$

Case III. Replacement of deficiency payments by additional tariffs on raw wool and wool products (Figure 4).

In Case I and Case II, we have considered the welfare cost of removing the raw wool tariff while maintaining producers' surplus unchanged in the raw wool sector. In Case III, we consider the welfare cost of employing a complete tariff system for raw wool instead of the present partial deficiency payments system. As illustrated in Figure 4, an additional tariff t_i^* is imposed on raw wool in place of former deficiency payments (AA' per unit of production).

Two outcomes are possible in the wool products sector as a result of the tariff increase. They are: (1) imposition of an additional compensatory tariff to prevent any change in producers' surplus in this sector due to higher input prices; (2) maintainance of wool products price at the former level, in which case there is a reduction in producers' surplus. Since the device of a compensatory tariff is at present employed in the U. S., it

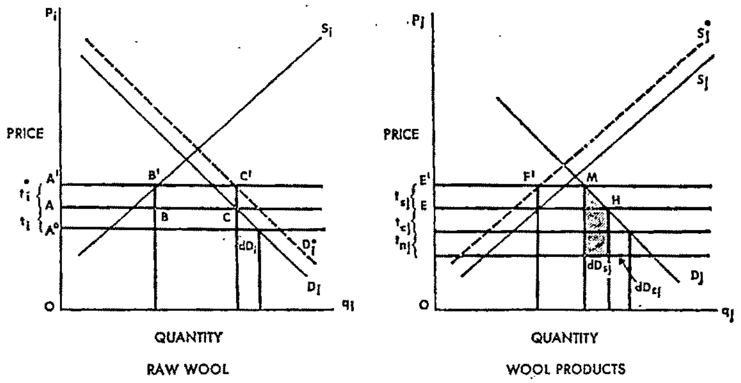


Figure 4. Case III: Replacement of deficiency payments by additional tariffs on raw wool and wool products

seems reasonable to anticipate its continuance in the event of a tariff increase for raw wool. Thus, an additional compensatory tariff t_{sj} is assumed to accompany the additional raw wool tariff t_i^*.

As in Case I, the simultaneous imposition of t_i^* and t_{sj} affects both sectors. Since in this instance, however, we are concerned with tariff imposition rather than tariff removal, the shifts of D_i to D_i^* and S_j to S_j^* are precisely the reverse of those that occurred in Case I.

In the raw wool sector, there is, as usual, no change in producers' surplus. The government, however, experiences a gain of $t_i^*A'C'$ because of the increase in custom revenue $t_i^*B'C'$ and the reduction in deficiency payments $t_i^*A'B'$. In the wool products sector, the gain in government revenue $t_{sj}F'M-(t_{cj}+t_{nj})dD_{sj}$ is offset by the loss in consumers' surplus of $t_{sj}E'M + \frac{1}{2}t_{sj}dD_{sj}$. There is no change in producers' surplus due to the employment of the additional compensatory tariff.

Combining the results of both sectors we obtain:

$$\begin{aligned} \text{Cost} &= t_{sj}E'F' + \tfrac{1}{2}t_{sj}dD_{sj} + (t_{cj} + t_{nj})dD_{sj} - t_i^*A'C' \\ &= \tfrac{1}{2}t_{sj}dD_{sj} + (t_{cj} + t_{nj})dD_{sj}, \text{ assuming} \\ t_{sj} &= t_i^*(A'C'/E'F'). \end{aligned}$$

This represents the cost to the economy when a complete tariff system is adopted in preference to a partial deficiency payments system and no change occurs in producers' surplus in either the raw wool or wool products sector.

Since Case I represents the gain from adopting a complete deficiency payments system, the results of both cases may be combined to compare two alternative methods of protection—deficiency payments and tariffs. In Figure 4, the additional cost of employing a complete tariff system, as opposed to a complete deficiency payments system, is given by

$$\tfrac{1}{2}t_{sj}dD_{sj} + t_{cj}(dD_{sj} + \tfrac{1}{2}dD_{cj}) + t_{nj}(dD_{sj} + dD_{cj}).$$

The Wool Products Supply Model

Whereas elasticity of demand values were based on existing demand studies [4, p. 81; 5, p. 677], elasticity of supply of wool products was obtained by means of a wool products supply model. A multiple linear regression model was used. Both linear and logarithmic versions of the supply equations were tested, and the latter were preferred because they provided a higher degree of explanation and higher "t" test values for most of the variables. Several alternative equations were considered for the wool supply model, with a different set of explanatory variables in each case. The simple least-squares method of estimation was used, since it was assumed that there was only one endogenous variable—wool products supply—in each equation.[7] In all cases, the equations were based on observations for the period 1948–65, and both six-months and annual data were employed.

The supply variable was the production of wool products—wool tops, yarns, broadwoven fabrics, blankets, and knit outerwear fabrics. Since raw wool is the basic raw material for the production of such items, mill consumption of raw apparel wool may be used to represent the supply of wool products in the wool textile industry. Supply of wool products was assumed to be determined mainly by four variables: price of wool products and input prices or prices of raw wool, labor, and capital.

A wholesale price index of wool products was used to reflect the price received by wool textile mills. This price index was composed of five categories of wool products: broadwoven fabrics, yarns, wool tops, blankets, and knit outerwear fabrics.[8] Since most firms manufacture to order, prices were unlagged or lagged for six months only. Raw material costs are the most important item in the cost structure of woolen and worsted textile mills [8, p. 72]. Since a satisfactory average price for all grades of raw wool was unavailable, the price of graded Territory shorn wool at Boston was used. This grade of raw wool accounts for a large part of the apparel wool used. A comparable grade of imported wool was also used—Australian 64s, 70s at Boston. This price series included the tariff on imported wool and thus represented the price paid by wool textile mills. Both price series tended to fluctuate parallel with one another, in agreement with the conclusions of Hermie [7, p. 37], thus providing a justification for the use of a representative raw wool price series. And since a time lag exists between the initial sale of raw wool and the production of wool products, prices were lagged from six months to a year.

---

[7] With the exception of the unlagged wool products price, the interest rate, and the bank rate, all the independent variables are lagged and thus predetermined. The bank rate and the interest rate may be considered exogenous variables. The price of wool products may also be considered an exogenous variable if we assume, as is the case with raw wool, that it is determined by world prices and the U. S. tariff, both of which are exogenous variables.

[8] The relative importance of the individual categories in the wool products wholesale price index is as follows: broadwoven fabrics 0.62, yarns 0.24, wool tops 0.08, blankets 0.03, and knit outerwear fabrics 0.03 [16, p. 39].

Labor costs are another important cost component in the wool textile industry products [8, pp. 72–73]. They were represented in this study by hourly wages paid by broad-woven fabric mills and were lagged from six months to a year to permit time for adjustment by the wool textile manufacturer. All price series and wages were deflated by the wholesale price index.

The cost of meeting current expenses and purchasing new capital and equipment was measured by the bank rate, which was the average of rates charged on short term loans, and the interest rate, given by the maturity per cent yield of industrial bonds. Phelps [9, p. 25] has discussed the important role that factoring plays in the financial operations of the textile industry so that these two series were assumed to include changes in the cost of services rendered by factoring firms.

The variables used in the wool supply model were as follows:

y is wool product production, no lag
x_1 is wholesale price index for wool products deflated by the wholesale price index for all commodities (WPI), no lag
x_2 is wholesale price index for wool products deflated by WPI, 6-months lag
x_3 is price of Territory fine wool, deflated by WPI, 6-months lag
x_4 is price of Australian 64s, 70s wool, deflated by WPI, 6-months lag
x_5 is bank rate, no lag
x_6 is bank rate, 6-months lag
x_7 is interest rate, no lag
x_8 is hourly wages, deflated by WPI, 1-year lag.

All variables are in logarithmic form.

The eight equations finally selected are given below. The variables without primes pertain to 6-month data; the variables with primes, to annual data.[9] Standard errors are enclosed in parentheses below their respective parameter estimates. The coefficients of multiple determination and the Durbin-Watson(d) statistics are also given:

$$\begin{array}{llll} (1) & y = 2.3242 + 3.1810x_2 & - 1.5535x_3 & - 0.9739x_5 \\ & \qquad\qquad\quad (0.9975) & \quad (0.4382) & \quad (0.1292) \\ & \qquad\qquad\quad R^2 = 0.755 & & \quad d = 1.43 \end{array}$$

---

[9] Due to multi-collinearity, it was not possible to include wages with either the bank rate or the interest rate. In the case of 6-months data, the bank rate was found to provide a more satisfactory explanation than either wages or the interest rate. This may reflect, in part, investment policies of the textile industry in the postwar period.

(2)
$$y = 2.5729 + 2.7959x_2 - 1.3286x_3 - 8.4641x_6$$
$$(0.9434) \qquad (0.4138) \qquad (0.1548)$$
$$R^2 = 0.715 \qquad d = 1.52$$

(3)
$$y = 6.9173 + 2.5444x_2 - 1.4688x_4 - 1.0688x_5$$
$$(0.6582) \qquad (0.3227) \qquad (0.1242)$$
$$R^2 = 0.792 \qquad d = 1.45$$

(4)
$$y = 7.1100 + 2.1034x_2 - 1.1940x_4 - 0.9342x_6$$
$$(0.6426) \qquad (0.3142) \qquad (0.1534)$$
$$R^2 = 0.742 \qquad d = 1.47$$

(5)
$$y' = 8.9496 + 2.1347x_1' - 0.9082x_3' - 0.7312x_5'$$
$$(0.6191) \qquad (0.2542) \qquad (0.1646)$$
$$R^2 = 0.857 \qquad d = 1.91$$

(6)
$$y' = 9.3753 + 2.8251x_1' - 1.2524x_3' - 0.8976x_7'$$
$$(0.6580) \qquad (0.3178) \qquad (0.2503)$$
$$R^2 = 0.820 \qquad d = 1.86$$

(7)
$$y' = 8.2608 + 3.1946x_1' - 0.9853x_3' - 1.5372x_8'$$
$$(0.6707) \qquad (0.3032) \qquad (0.4672)$$
$$R^2 = 0.805 \qquad d = 2.07$$

(8)
$$y' = 8.6118 + 1.6736x_1' - 0.4970x_4' - 1.2001x_8'$$
$$(0.6366) \qquad (0.5332) \qquad (0.5833)$$
$$R^2 = 0.678 \qquad d = 1.99$$

Estimates of the coefficients, with the exception of equation (8), were found to be statistically significant at the 1 percent level. All the signs of the coefficients are satisfactory and are in agreement with economic theory—a positive relationship between supply and the price of its product, with an inverse relationship between supply and input prices. The Durbin-Watson test for serial correlation produced results that were inconclusive in the case of 6-months data and showed no evidence of serial correlation for annual data.

Elasticity values estimated by using 6-months data were fairly similar to those estimated by means of annual data. Values were elastic in all instances and ranged from 1.67 to 3.19.

Measurement of the Cost of Alternative Methods of Protection for Raw Wool

The gain or loss arising from the adoption of alternative methods of protection for raw wool was examined for 1963, considered to be a representative year for the period after 1961 because standard tariff rates for wool products have been employed since then.

Case I. Gain from removing the raw wool and compensatory tariffs

The net gain was defined as

$$t_{nj}dD_{cj} + \tfrac{1}{2}t_{cj}dD_{cj}$$

where

t_{nj} = net tariff on wool products
$t_{cj} = dp_j$ = compensatory tariff on wool products

dD_{cj} = change in domestic consumption of wool products when the compensatory tariff is removed.

Then

$$\begin{aligned} dD_{cj}(t_{nj} + \tfrac{1}{2}t_{cj}) &= \frac{dD_{cj}}{dp_j}\, dp_j(t_{nj} + \tfrac{1}{2}t_{cj}) \\ &= \epsilon_j \frac{D_j}{p_j}\, t_{cj}(t_{nj} + \tfrac{1}{2}t_{cj}) \\ &= \epsilon_j V^D_j k_{cj}(k_{nj} + \tfrac{1}{2}k_{cj}) \end{aligned}$$

where

ϵ_j = elasticity of domestic demand for wool products
$V^D{}_j$ = value of domestic consumption of wool products
$k_{nj} = t_{nj}/p_j$
$k_{cj} = dp_j/p_j = t_{cj}/p_j$

and

p_j = domestic price of wool products in 1963.

Table 1 gives the gain from replacing the present partial deficiency payments system by a complete deficiency payments system.

The variables k_{nj} and k_{cj} were obtained by dividing duties collected under the net and compensatory tariffs, respectively, by the total value of imports

Table 1. Gain from removing the raw wool and compensatory tariffs (1963)

ϵ_j	V_j^D	k_{cj}	k_{nj}	Gain	Gain as a percentage of the value of domestic consumption
	million dollars			million dollars	
0.5	1,291	0.0805	0.2142	13.17	1.0
1.0	1,291	0.0805	0.2142	26.34	2.0

including compensatory and net tariffs. Summation of the value of imports and the value of domestic shipments provided a measure of V_j^D. Two values of elasticity of demand— 0.5 and 1.0—based on previous studies of demand for raw wool, were employed.[10] Estimates of the gain ranged from \$13 to \$26 million and accounted for 1–2 percent of the value of domestic consumption. This gain may also be considered the cost to the economy of employing a partial rather than a complete deficiency payments system.

Case II. Cost of removing the raw wool tariff only

The cost was defined as

$$\begin{aligned} & t_{nj} dS_{cj} + \tfrac{1}{2} t_{cj} dS_{cj} \\ & \quad = \frac{dS_{cj}}{dp_j} dp_j \left(t_{nj} + \tfrac{1}{2} t_{cj}\right) \\ & \quad = \eta_j \frac{\bar{S}_j}{p_j} t_{cj} \left(t_{nj} + \tfrac{1}{2} t_{cj}\right) \\ & \quad = \eta_j V_j^S k_{cj} \left(k_{nj} + \tfrac{1}{2} k_{cj}\right) \end{aligned}$$

where

V_j^S = value of domestic production of wool products,

η_j = elasticity of domestic supply of wool products and the other terms are as defined earlier.

In a similar manner, relative cost, or cost as a percentage of the change in producers' surplus, reduces to

$$\frac{\eta_j k_{nj} + \tfrac{1}{2} \eta_j k_{cj}}{1 + \tfrac{1}{2} \eta_j k_{cj}}$$

Table 2 gives the cost when the raw wool tariff only is removed. The wool products supply model furnished the necessary supply elasticities. For purposes of comparison, cost estimates for η_j equal to unity were also obtained.

The cost of protection is considerable, both in absolute and relative terms. Absolute cost ranged from \$23 to \$75 million; relative cost, or cost as a percentage of the change in producers' surplus, ranged from 24 to 72 percent, depending on the elasticity value used. Thus, each dollar gained by the

---

[10] Studies by Donald [4, p. 81] and Ferguson and Polasek [5, p. 677] give elasticities of demand for raw wool of 0.32 and 0.56 respectively. If we assume that the elasticity of demand for raw materials is less than the elasticity of demand for products manufactured from the same raw materials, such estimates provide a lower limit on the elasticity of demand for wool products. See Foote's discussion of elasticities of demand at various marketing levels [6, pp. 106–108]. The existence of many substitutes for wool products, owing to the growth of the man-made fiber industry, and the importance of raw material costs to the consumers of wool textile products also justify the belief in a relatively elastic demand for wool products.

Table 2. Cost of removing raw wool tariff only (1963)

Eq.	η_j	V_j^S	k_{cj}	k_{nj}	Cost	Cost as a percentage of change in producers' surplus
		million dlolars			million dollars	
—	1.00	1,145	0.0805	0.2142	23.36	24
8	1.67	1,145	0.0805	0.2142	39.01	40
4	2.10	1,145	0.0805	0.2142	49.06	49
5	2.18	1,145	0.0805	0.2142	50.92	51
3	2.54	1,145	0.0805	0.2142	59.33	59
2	2.80	1,145	0.0805	0.2142	65.41	64
6	2.83	1,145	0.0805	0.2142	66.11	65
1	3.18	1,145	0.0805	0.2142	74.28	72
7	3.19	1,145	0.0805	0.2142	74.52	72

wool textile industry under this new method of protection would cost the economy from 24 to 72 cents. The high cost is really a reflection of added protection of the domestic wool textile industry, since the compensatory tariff is continued in spite of the removal of the raw wool tariff. Adoption of this method of protection brings a net loss rather than a net gain to the economy, although it does benefit the wool products producer.

Case III. Cost of replacing deficiency payments by additional tariffs on raw wool and wool products

The cost was defined as

$$\tfrac{1}{2}t_{sj}dD_{sj} + (t_{cj} + t_{nj})dD_{sj}$$

where

$t_{sj} = dp_j =$ additional (compensatory) tariff on wool products

$dD_{sj} =$ change in domestic consumption of wool products when t_{sj} is employed.

This may be rewritten as

$$\frac{dD_{sj}}{dp_j}\, dp_j(\tfrac{1}{2}t_{sj} + t_{cj} + t_{nj})$$

$$= \epsilon_j \frac{D_j}{p_j} t_{sj}(\tfrac{1}{2}t_{sj} + t_{cj} + t_{nj})$$

$$= \epsilon_j V^D{}_j k_{sj}(\tfrac{1}{2}k_{sj} + k_{cj} + k_{nj})$$

where $k_{sj} = t_{sj}/p_j$ and the other terms are as defined earlier.

Table 3 gives the cost of replacing the present partial deficiency payments system by a complete tariff system. The additional compensatory

Table 3. Cost of replacing deficiency payments by additional tariffs on raw wool and wool products (1963)

ϵ_j	V_j^D	k_{cj}	k_{nj}	k_{sj}	Cost	Cost as a percentage of the value of domestic consumption
	million dollars				million dollars	
0.5	1,291	0.0805	0.2142	0.0947	20.92	1.6
1.0	1,291	0.0805	0.2142	0.0947	41.83	3.2

tariff k_{sj} was obtained by comparing average prices received by farmers with support prices for raw wool and relating this difference to the wool products price. As in Case II, the economy endures a net loss when it adopts this method of protection. The loss ranged from $21 to $42 million and accounted for 2 to 3 percent of the value of domestic consumption. This result also provides an estimate of the gain to the economy when a partial deficiency payments system rather than a complete tariff system was adopted in 1954. When we combine the results of Case I and Case III, we can compare two methods of protection—complete deficiency payments system and complete tariff system. The difference between the two methods ranges from $34 to $68 million, a difference that is accounted for by the absence of a consumption cost under the deficiency payments system.

Conclusions

The gain or loss resulting from the adoption of three alternative methods of protecting raw wool in the United States was calculated for the year 1963. In all cases, producer price (and hence, producers' surplus) was maintained unchanged in the raw wool sector.

The gain from the removal of the raw wool and compensatory tariffs (Case I) varied from $13 to $26 million and from 1 to 2 percent of the value of domestic consumption of wool products, depending on the particular elasticity of demand used. When only the raw wool tariff was removed, however, the economy endured a loss rather than a gain, ranging from $23 to $75 million. This cost arose from the stimulation of domestic production of wool products in response to lower input prices and was related to elasticity of supply of wool products. Relative cost, or cost as a percentage of the change in producers' surplus, in the wool products sector ranged from 24 to 72 percent, depending on the particular elasticity of supply used. Thus, every dollar transferred to the wool products sector by this method of protection cost the economy from 24 to 72 cents in terms of resource misallocation. The results of Case II indicate the necessity for removing both the raw wool and compensatory tariffs if the economy is to obtain a net gain.

The replacement of the present partial deficiency payments system by a complete tariff system (Case III) cost the economy from $21 to $42 million, or from 2 to 3 percent of the value of domestic consumption. This result is of interest in that it indicates the gain in 1963 to the economy in utilizing a partial deficiency payments system in place of a complete tariff system as a method of protecting the raw wool producer. Case I, on the other hand, indicates the potential gain foregone by the economy in 1963 in not employing a complete deficiency payments system. The combined results of Case I and Case III give an additional cost of $34 to $68 million when tariffs rather than deficiency payments are used to protect the raw wool sector. This cost is calculated on the basis of unchanged producers' surplus in either sector and reflects the absence of a consumption cost under a complete deficiency payments system.

The limitations of the present study must be acknowledged. In addition to the usual limitations of partial equiliblium analysis, it neglects the dynamic effects of trade restrictions. Its scope is also limited to the impact of alternative methods of protection for raw wool on the economy. The cost to the economy of maintaining protection in either the raw wool or wool products sector was not investigated; such a study undoubtedly needs to be done.

The most important result of the study is the demonstration of the relationship between method and cost of protection. In particular, the results of Case I provide us with an estimate of the cost of maintaining the present system of protection for raw wool—a cost which could be removed without changing producers' surplus in either the raw wool or wool products sector.

Changes in the existing method of protection may also have implications for the wool sector in the long run. It is possible that the higher price of raw wool has provided an incentive for the substitution of synthetics for wool [1, p. 144]. Such a development cannot be considered to be in the best interests of the domestic wool producers, since the entire clip of the domestic producer is sold to domestic mills [12, p. 12]. Thus, given the existence of a domestic wool support program, both the wool growers and the economy have much to gain by eliminating the raw wool and compensatory tariffs and substituting increased deficiency payments.

Appendix

Data Used in the Wool Products Supply Model

The supply of wool textile products was represented by mill consumption of apparel wool (U.S. Department of Agriculture, *Wool Statistics and Re-*

lated Data: 1920–64, and *Supplement for 1965*, ERS, Stat. Bul. No. 363, July 1965, August 1966, Table 84).

The wholesale price indexes for wool products and for all commodities were the indexes prepared by the U.S. Department of Labor, Bureau of Labor Statistics (U.S. Department of Commerce, *Survey of Current Business*, and U.S. Department of Commerce, *Business Statistics: A Supplement to Survey of Current Business.*) Two series were employed to estimate the price of raw wool to the mills. The first series was graded territory shorn wool, fine good French combing and staple, clean basis, Boston, (U.S. Department of Agriculture, *op. cit.*, Table 168). The second series was Australian wool, 64's, 70's, good top-making, clean basis, Boston, duty-paid, (U.S. Department of Agriculture, *op. cit.*, Table 200).

Labor costs were represented by average hourly earnings of production and related workers in the woolen and worsted division and by average hourly earnings of production workers in weaving and finishing broad woolens (Special Communication from Robert O. Dorman, U.S. Department of Labor, Bureau of Labor Statistics and U.S. Department of Labor, Bureau of Labor Statistics, *Employment and Earnings Statistics for the United States, 1909–65*, BLS Bul. No. 1312-3, 1965). Both series overlapped for a period of three years (1958–60) and, since they were almost identical, were combined to form a single series.

The interest rate used was the yield to maturity of high grade industrial bonds (Standard and Poors' Corporation, *Standard and Poors' Trade and Securities Statistics: Security Price Index Record.*) The remaining variable employed to estimate cost of capital, was the bank rate on business loans in nineteen cities in the United States (U.S. Department of Commerce, *Business Statistics.*)

Capitalized Values of Tobacco Allotments and the Rate of Return to Allotment Owners*

JAMES A. SEAGRAVES

Tobacco allotments have been salable only along with the farms to which they are attached. Multiple regression allows one to isolate that part of total land value accounted for by allotments. Capitalized values of flue-cured tobacco allotments were estimated for the period 1934–62. The ratio of annual earnings to these capitalized values, or the rate of return, fell from about .75 in the years 1944–46, when the program was first really effective, to a level of .16 for the period 1957–62. This decline reflects a dramatic increase in investor confidence in the future of the tobacco program and places tobacco allotments, which are widely thought to be highly profitable as monopoly rights go, in a class of relatively riskless investments. Government programs that reduce the risk of farm ownership are bound to increase the value of the assets and thereby reduce the rate of return. The rate of return allows us to predict the fall in capitalized value that will accompany future changes in expected income.

THIS study is not meant to be a defense of or an attack upon the tobacco program. It began as an effort to understand the distributive process. The results conflict sharply with the beliefs of those who argue that labor has benefited from the program. Even though owner-operators supply the majority of the labor, it does not follow that opportunity returns to labor are therefore inseparable from returns to other factors. Nor is there any logical reason for a restriction of production to increase the demand for labor; and certainly nothing has been done under the program to reduce the supply of workers. North Carolina has more farmers than any other state, and many of them grow tobacco. The program clearly has helped the State, and some of its land owners, a great deal.[1]

The main results of the study are summarized in Table 1. Independent estimates were obtained for the annual net revenue and the capitalized value of the right to produce a pound of flue-cured tobacco. Average values of these series, converted to constant dollars, were then calculated for approximately three decades, between 1934 and 1962. Net revenues were relatively constant during this period, increasing from 19.2 cents per

---

pound in the first decade of the program to 25.6 cents per pound for 1943–52, and falling to 23.7 cents per pound in the most recent decade; but capitalized values steadily increased from 34.5 cents per pound to $1.51 per pound in the last decade studied. How is it possible that net revenues fell 7 percent between 1943–52 and 1953–62, while the amount paid for the right to grow tobacco increased 138 percent? Why did the rate of return on the capitalized value of tobacco allotments fall as drastically as indicated in Table 1?

One reason investors bid up the price of these allotments was that con-

---

predicting rational firm behavior in the light of proposed program changes; and (d) distribution of program benefits among farm resources. This article belongs in (d). To describe briefly some of these studies, by categories: (a) Williamson and Toussaint [29] gave us a picture of the strong political support for the tobacco program; and Williamson and Brooks [28] explained how poundage controls could work some five years before they were adopted. (b) Johnson [15] measured social costs to the U. S. of restricted production and found them to be more than offset by the increased value of exports. He derived an elasticity of —2.0 for our export demand from assumptions about demand and foreign supply elasticity. Capel [4] used time series data from 11 importing countries and estimated that foreign demand for our exports fell within the range of —0.61 to —2.27. (c) Acreage reserve was studied by Coltrane [6]. The program was short-lived and had little impact. Lease and transfer provisions have been much more significant. Bradford and Toussaint [3] studied the possibilities for transferability before the program actually started. Their provisions concerning price per pound at which allotments would be traded were substantiated by surveys reported by Bordeaux, Hoover and Toussaint [2]. Hoover [13] has obtained estimates of rents paid per pound for all the flue-cured tobacco producing regions from Virginia to Florida. (d) Mason [18] was one of the first economists to estimate value of tobacco allotments and discuss distributional implications. He estimated that an acre of tobacco allotment added $300 to $600 to the value of a farm in 1945. Maier, Hedrick and Gibson [16] used multiple regression techniques with actual farm sales in Pittsylvania county, Virginia, and in certain Eastern North Carolina counties to estimate the values of flue-cured tobacco allotments per acre for 1954–1957. Reductions in allotment acres were associated positively with increases in allotment values per acre. Allotment values were lower where non-farm wages were higher. Hedrick [10] estimated landlord and cropper tenant incomes for the period 1922–1966 from survey data. A recently issued USDA Bulletin by Hedrick, Tolley, and Bach [11] summarizes this study.

[a] North Carolina Department of Agriculture [20 and 21]. Average yields and prices for New Belt, Type 12 tobacco.

[b] United States Department of Agriculture [26]. Based on private communication with J. S. Chappell and D. D. Osburn, 1963, the Crop Reporting Board wage rate estimates were multiplied by 0.926 to estimate wage rates for tobacco production.

[c] Net revenue is estimated by subtracting from total revenue (yield×price) labor costs, variable costs, and land rent. Variable costs and the quantity of labor per acre are based on linear trends connecting the data from these farm management studies: Greene [9], cost data for 1932–1934; Chumney and Vermeer [5], cost data for 1959 and

terms of yields and prices. In 1933 the price was supported, though there were no acreage controls. The combination of higher average yields and a higher price led to much higher net returns. Acreage of tobacco in the New Belt was reduced from 352,000 acres in 1933 to 250,000 acres in 1934. Yields again increased, and prices rose from 16.4 cents per pound in 1933 to 29.7 cents in 1934, again dramatically increasing net returns. In 1939, growers "voted out" acreage control and planted a record 425,000 acres with record yields. The price fell drastically and so did net revenue—to $4.51 per acre from an average of $88.00 per acre for the preceding years. Acreage was limited to 245,000 acres in 1940, and the price increased slightly. Relatively low prices in 1955 and 1956 were associated with high production of "slick" tobacco at a time when darker "bodied" varieties were wanted by the export trade and makers of filter cigarettes. In the net revenue calculation, these lower prices were more than offset by higher yields. When support was withdrawn in 1957 for several high-yielding "slick" varieties of tobacco at the same time that acreage was cut 20 percent, the result was a sizable increase in price and net revenue in 1958.

Tobacco prices since World War II, expressed in constant 1957–59 dollars, generally have stayed within a range of 50–70 cents per pound, focusing in recent years on 55–65 cents (see Table 2). The same stability is characteristic of net revenues per pound, which stayed within a range of 15–35 cents per pound (in 1957–59 dollars) and were generally between 20 and 30 cents per pound. Of course, net revenue *per acre* increased steadily as yields increased during this period, but the net revenue of a given size farm remained fairly constant as the number of allotted acres was declining.

Capitalized Values of Allotments

Because the cost of using data on individual farm sales would have been prohibitive, capitalized values had to be estimated from readily

---

labor data for 1956 and 1959; Coutu and Mangum [7], cost data for 1959; and Hole and Vermeer [12], labor data for 1941–1942 and 1957–1958.

Variable costs in dollars per acre are approximated by:

$$VC = 18.61 + 7.71t \quad (t = 0 \text{ in } 1930).$$

Labor in hours per acre is approximated by:

$$\text{Hours} = 376 + 4.97t \quad (t = 0 \text{ in } 1930).$$

Labor increases because yields have been increasing. Rent per acre of cropland without allotment is estimated from the net tobacco income of $9 per acre for the years 1930–1932. After 1933, it was assumed to increase following a linear trend to $25 per acre in 1962, which was approximately the net income from corn. The trend is:

$$\text{Rent} = 9.00 + .55t \quad (t = 0 \text{ in } 1933).$$

[d] The consumer price index of the Department of Labor, as published in *Agricultural Statistics* [25], was used as deflator.

available time series. With the use of Crop Reporting Service and U.S. Census of Agriculture [27] data, it was possible to estimate the value of total farm land minus buildings for each of twenty counties in the "New Belt" of Eastern North Carolina and for each year from 1930 to 1962. These estimates of total land value in each county, together with the recorded pounds of tobacco produced the previous year, provided the basis for using multiple regression to isolate the net value of tobacco allotments per pound.

Using data for 20 counties. Manning [17] estimated allotment values per pound for 1951–1963. His data included the value of farmland, pounds of tobacco production for previous years, acres of cropland, acres of other land, and acres of peanut and cotton allotments. His regression model for explaining W_{ij}, the total value of all farmland in county i and year j, was

$$W_{ij} = \sum_{j=51}^{62} B_{1j} X_{1ij} g_j + \sum_{k=2}^{5} (B_k X_{kij} + C_k X_{kij} t_j) + e_{ij}$$

where

X_{1ij} is the county allotment times the average yield in the previous year in pounds of tobacco,
X_{2ij} is the county cotton allotment in acres,
X_{3ij} is the county peanut allotment in acres,
X_{4ij} is acres of cropland for the county,
X_{5ij} is acres of other land for the county,
e_{ij} is a random error,
t_j is the year, and
$g_j = 1$ for year j and zero otherwise.

(Capital letters B and C represent population or "true" parameters and the corresponding small letters in Tables 3 and 4 represent regression estimates.)

Several of these series were highly intercorrelated, which led to negative coefficients for cotton allotments and other land. As a result, these variables were deleted from the regression equation reported in Table 3. Also, this regression equation was obtained without a constant term since it was difficult to conceive of the meaning that a constant term would have in a value equation that explains the total value of farmland in each county. The results were compared with those of Maier, *et al.* [16], obtained from actual farm sales data for the years 1954–57 for three counties. The estimates were sufficiently similar to allow acceptance of these

Table 3. Regression coefficients for estimating tobacco allotment values from county land values, 1951–1963

Year	Coefficient b_1 (Tobacco allotment values)	t−ratios
	dollars per pound	
1951	.76	8.44

Increment in value of cropland, c_4	$ 8.19/acre/year	2.44

Number of observations: 260 (20 counties × 13 years).
Since no constant term was included, the simple correlation coefficient of the predicted and observed values, $r_{y\hat{y}}$, was calculated, instead of R^2, $r_{y\hat{y}} = 0.79$.

aggregate county land value data as a basis for estimating allotment values.

The same procedure was used to obtain the allotment values per pound for 1934–1950, listed in Table 4. In this period, cotton and peanut allotments did not have significant effects on total farm value. When both cropland and other land were included in the same regression, the annual incremental coefficient for other land was negative. The regression equation given in Table 4 was chosen from among several that were tried. A technical bulletin by Seagraves and Manning [23] contains a more complete discussion of data sources and regression equations tried and suggestions for analysis of such combined cross-section and time-series data.

The regression coefficients, which estimate the market value of tobacco allotments per pound, were highly significantly different from zero after 1944 (t-ratios greater than 7) and were relatively insensitive to other variables besides cropland included in other models that were tried. The results from Tables 3 and 4 are brought together in the first column of Table 5. Estimated allotment values per pound fluctuate from year to year mainly because actual yield data for counties in the previous year were used to obtain them. Whenever overall production in these counties was high, the resulting estimate of allotment value for the following year

Table 4. Regression coefficients for estimating tobacco allotment values from county land values, 1934-1950

Year	Coefficient b_1 (Tobacco allotment value)	t – ratios
	dollars per pound

would be low, and vice versa. Hence, much of the extreme fluctuation disappears when allotment values per pound are multiplied by yields for the previous year to obtain the estimates of allotment values per acre. Allotment values per acre increased steadily from about \$500 per acre in 1945–48 to \$3000 per acre in 1959–62. Net revenues were based on current yields and are generally higher when yields are higher. The rate of return is calculated on an annual basis by dividing the net revenue by the capitalized value. The results, presented in Table 5, show a decline proportionate to the increase in allotment values, but the values are somewhat erratic.

Alternative Explanations of the Rate of Return

Two alternative ways to "explain" the indicated decline in the rates of return (Table 5) are (1) smaller discounts for uncertainty, and (2) longer time horizons. Both are based on the present value formula,

$$V_t = \sum_{n=t}^{N} \frac{E(R_n)}{(1+r)^n}, \tag{1}$$

in which V_t is the capitalized value of an asset at time t; $E(R_n)$ is the

[a] Annual net revenue divided by capitalized values.
Source: Tables 2, 3, and 4.

expected net revenue attributed to the same asset in each future year n; and r is the long-run future discount rate.

Assuming, for purposes of simplicity, that expected annual net revenues for future years are constant and can be represented by one number, $E(R)_t$, for all future years, then the present value formula becomes

$$V_t = E(R)_t \sum_{n=t}^{N} \frac{1}{(1+r)^n} . \tag{2}$$

Further simplifications are commonly applied. For example, an infinite stream of future incomes, $E(R)_t$, is often assumed. In this case,

$$V_t = \frac{E(R)_t}{r}, \quad \text{or} \tag{3}$$

$$r = \frac{E(R)_t}{V_t}.$$

Assuming further that expected future net incomes, $E(R)_t$, are equal to current incomes, R_t, then rates of return (as presented in Table 5) are the same as discount rates, r, with infinite time horizons. Year-to-year fluctuations have been smoothed out of this rate of return series by taking a weighted average of the five most recent years; the results are presented in Table 6. (A preferable procedure may have been to smooth yield series before calculating net revenues and capitalized values.) The smoothed ratios show a steady decline, from $r = .87$ in 1945 to $r = .14$ in 1959. These data suggest that there has been a dramatic reduction in uncertainty, profit, or the return on current investments in tobacco allotments since 1945. The interest rate on new agricultural loans of the Federal Land Bank, also

Table 6. Weighted average of recent rates or return, interest rates on new agricultural loans, and calculated time horizons, 1945-1962

Year	Weighted averages of rates of return[a]	Interest rate on new agricultural loans[b]	Time horizon implied, in years[c]
1945	.87	.04	1.5
6	.82	.04	1.5
7	.65	.04	1.5
8	.50	.04	2.0

1960	.14	.06	9.5
1	.16	.06	8.0
2	.16	.06	8.0

[a] Diminishing weights were arbitrarily assigned to the five most recent years, as follows:

$$\bar{r}_t = .30r_t + .25r_{t-1} + .20r_{t-2} + .15r_{t-3} + .10r_{t-4}$$

where the r's are the rates of return from Table 5.

[b] Federal Land Bank rates, as published in *Agricultural Statistics* [25].

[c] Obtained from interest tables for an annuity whose present value is 1.

shown in Table 6, can be thought of as the long-run future discount rate without uncertainty. The difference between the two would be the "net discount for uncertainty," assuming, as a matter of convenience, that the incomes would go on forever.

Alternatively, the rate of return ratio and the riskless rate of interest was used to find (from interest tables) the number of years in the planning horizon, N.[2] The resulting estimates, to the nearest half-year, are presented in the last column of Table 6; they show a lengthening of the time horizon from 1.5 years in 1945 to 9.5 years in 1959. The number of years in the planning horizon was virtually constant from 1957–1962, reflecting practically no change in expectations about the future of the program during this period.

The above two "explanations" of the capitalization process, changes in uncertainty and variable time horizons remain extremely superficial. One source of superficiality is the naive expectations model in which expected future annual incomes are assumed to be equal to current annual income.

$$E(R)_t = R_t.$$

An alternative is to use distributed lags of past incomes based on an expectations model, such as

$$E(R)_t = \left(\frac{R_{t-1}}{E(R)_{t-1}}\right)^{\delta} E(R)_{t-1} e_t, \tag{4}$$

in which the ratio of the actual to expected revenue last year raised to the power δ provides the adjustment factor which is multiplied by last year's expectations to get current expectations of all future incomes, $E(R)_t$. The random error, e_t, is assumed to be multiplicative. This has the same effect as saying that expected future revenue is a weighted average of past revenues. Nonlinear regression procedures were used to estimate δ instead of assuming that it was equal to 1, as was done above. The results

---

[2] From equation (2), we have

$$\sum_{n=t}^{N} (1 + r)^n = \frac{E(R)_t}{V_t}.$$

Assuming a rickless interest rate, r, interest tables can be used to find N, the number of years for the annuity of amount $E(R)_t/V_t$, whose present value is 1, *i.e.* V_t. Simply calling N a "planning horizon" does not make it one. Letting all of the uncertainty in $E(R)_t$ be expressed in a smaller N is just as artificial as saying the planning horizon is infinite and letting all of the uncertainty be expressed in r. Objective studies of actual planning horizons and changes in them would require very carefully formulated hypotheses. Incidentally, I found no empirical relationship between presidential or congressional elections and these indicators of uncertainty which would support my hypotheses about the effect of these political changes.

were disappointing mainly because of the deficiencies in the data mentioned earlier.

Predicting Changes in Capitalized Values

The author is interested in the effects of program changes, estimates of elasticities, and statements involving multipliers, such as: "a price increase of 1 cent per pound for tobacco, *ceteris paribus*, is expected to lead to a 6¼ cents per pound increase in allotment values;" or, "a wage rate increase of 10 cents per hour increases production costs 2½ cents per pound and reduces allotment values 15.6 cents per pound." He has concluded that simple synthetic estimates should usually be calculated as a check on regression and other estimates.

With respect to elasticities, Manning [17] developed a simultaneous equations model which should have allowed for all the complex effects of something like a change in tobacco allotments on wages, prices, and allotment values. His data were not precise enough, however, to quantify all of these interactions. He found an elasticity of allotment values with respect to an exogenous tobacco price change (no change in allotments) of slightly less than 1. (The author's synthetic estimate of $dC/dP \cdot P/C$ is $6\frac{1}{4} \cdot 0.60/1.70 = 2.2$.) Manning concluded, "To the extent that prices and time were collinear for the sample there is some confounding of their effects. The sample period [1951–63] was one in which tobacco prices rose about $.10 and the allotment values rose by about $2000 [per acre]. If the interest rate and time variable are aggregated (being very highly correlated), they explain about $1,800 of this increase . . ." [17, p. 31]. Low price variation made it impossible for him to measure the net effects of an exogenous tobacco price change. Still, I believe that this can be a fruitful approach and that it needs to be continued, perhaps with an aggregate demand function and certain other constraints imposed on the system.

Hendrick [10] studied the program's long-run effects on returns to the landlord and the tenant. He found that the returns to cropper labor and the general opportunity returns to labor were "approximately equal in the long run or that tenure arrangements were flexible" [10, p. 71]. This implied that rent was the only residual claimant. Using production theory, he established an equation relating the changes in rent over time to yield, price, wage, labor efficiency, variable costs and their interactions. This allowed him to estimate that tobacco price had a positive effect of $271 and that wage increases had a negative effect of −$295 per acre on tobacco allotment rents in North Carolina between 1925 and 1960. The overall effect for these 35 years was an addition to rent of $177 per acre. He concluded that the elasticity of allotment values with respect to the price of tobacco is about 5 [10, p. 88]. In addition, Hedrick considered the reductions in the number of allotted acres and found that the total rental value of tobacco acres on a typical North Carolina farm would have increased very little from 1947 to 1960. Increases in rent per acre from $109 to $214 were almost completely offset by reductions in allotted acres from 9.2 to 5.3 [10, p. 102].

A percentage distribution of total revenue, based on the budgeted costs of Table 2, is presented in Table 7. Net revenue has been a surprisingly constant proportion of total revenue since the support program began. Labor costs have been increasing steadily since the depression, but there is no logical reason to believe that the tobacco program, which restricted production, would have contributed to these increased wage rates. Land and variable costs have declined in relative importance.

Table 7. Percentage distribution of total receipts among costs and net revenue per acre of flue-cured tobacco in the "New Belt" of Eastern North Carolina, 1930-1962

	Total revenue, dollars per acre in current dollars	Percentage each item is of total revenue			
		Land	Variable costs	Labor	Net revenue to allotment
1930–33	95	9.48	31.79	43.79	14.94
1934–42	237	4.96	33.86	21.78	39.40
1943–52	595	2.85	25.80	31.71	39.64
1953–62	969	2.32	23.81	32.62	41.25

Source: Table 2.

Many of the relevant elasticities or multipliers can be estimated quite simply from three numbers: the elasticity of demand for tobacco, the net revenue percentage, and the ratio of capitalized values to annual net revenues. Johnson [15] estimated the elasticity of domestic plus foreign demand for U. S. production at about −.55. Using this estimate, plus an assumption that net revenues to allotments are 40 percent of total revenue, as in Table 7, one can calculate an elasticity of net revenue (or allotment value) with respect to tobacco price. A 1.0 percent price increase results in a 0.45 percent increase in total revenue (price increases 1.0 percent and quantity decreases 0.55 percent), which is the same as a 0.45 ÷ 0.40 = 1.12 percent increase in net revenue. Assuming that the ratio of capitalized values to net revenues is constant, the percentage change in allotment values as a result of a 1.0 percent increase in price also would be 1.12. (This is for a change in price along one demand curve, as distinct from the elasticities mentioned above, which were based on an exogenous increase in demand.)

If one wanted to calculate an absolute multiplier, as opposed to an elasticity, knowledge of the price/earnings ratio also would be necessary. A price/earnings ratio of 6.25 is simply the reciprocal of the rate of return of 0.16 in Table 6. What would be the effect of a 10 cent per hour increase in the wage rate on allotment values? The labor requirement is about 1/4 hour per pound, so that net revenue will be reduced by 2 1/2 cents. This results in a decrease in allotment values of 6.25 (2 1/2 cents), or 15.6 cents per pound.

The price/earnings ratio is assumed to be stable in the above example. One also could imagine changes which affect the general level of confidence in the program. In such cases, one would need to quantify the change in the price/earnings ratio in order to calculate these elasticities and multipliers.

Conclusions

Budgeting procedures provide estimates of the annual net earnings per pound of tobacco allotment that are reasonably close to the actual rents paid.[3] Different regression procedures and data sources provide consistent estimates of the capitalized value of allotments. Combining these, the rate of return gives a measure of the distributive impact of the tobacco program from the standpoint of new investors or any existing farmers who plan to retain ownership of allotments during the coming year. Ownership of a farm can be thought of as holding a portfolio of assets, each with distinctive elements of risk and personal utility. The positive relationship between rates of return and risk in the aggregate has been explained by Farrar [8], Sharp [24], and others. Government programs that reduce the risks of farming are almost bound to increase the value of assets and thereby reduce the rate of return on investments in farming.

Nonproducer Cooperative Interests and the Antitrust Laws*

RONALD D. KNUTSON

Cooperatives' ability to enlist the assistance of non-producer and/or noncooperative firms in their marketing efforts has been severely limited by recent Supreme Court decisions. In *Case-Swayne Co. v. Sunkist Growers, Inc.*, the court held that Sunkist, with nongrower members, was not a Capper-Volstead cooperative and therefore was not entitled to Capper-Volstead exemption from prosecution under section 1 of the Sherman Act. Although the case provides a much needed guide for cooperative activity, it did not explicitly define what constitutes a producer. Nor did it provide an indication of the extent to which a cooperative can control or increase its share of the market and still not be held in violation of section 2 of the Sherman Act.

THE EXTENT to which cooperatives are able to organize to exercise influence upon the marketing of farm products and to enlist the assistance of nonproducer and/or noncooperative firms in their marketing efforts has an important influence upon the cooperative movement. A recent United States Supreme Court decision—*Case Swayne Co. v. Sunkist Growers, Inc.* [5]—helps to clarify some of these questions. At the same time, it raises new questions with respect to the definition of a producer and the extent of nonproducer participation allowed in a cooperative under the Capper-Volstead Act. This article is designed to provide some insight and to promote discussion of these questions.

In *Case-Swayne v. Sunkist*, the plaintiff (Case-Swayne) brought action seeking treble damages under section 4 of the Clayton Act [5] from Sunkist for alleged monopoly and attempt to monopolize in violation of sections 1 and 2 of the Sherman Act [10]. Case-Swayne was an independent manufacturer of single strength orange juice. It accused Sunkist of having conspired with its noncooperative packing house members to limit the quantity of product citrus fruit available to Case-Swayne.

Sunkist, a federated cooperative, controlled approximately 70 percent of all of the oranges produced in California and 67 percent of the oranges diverted to product use. All of the Sunkist local affiliates contract with Sunkist to market all of their fruit. The local associations, in turn, contract with their growers.

Case-Swayne had no problem purchasing product oranges when Sunkist operated none of its own processing facilities. However, when juice and other citrus products became profitable, Sunkist set up its own pro-

---

cessing facilities. It then sold to independent processors, such as Case-Swayne, only when it was unable to process its own fruit. As Sunkist increased its processing capacity, Case-Swayne found it increasingly difficult to obtain fruit. The alleged violations of the Sherman Act arose out of the combination of Sunkist's dominant control of the California-Arizona orange crop, its vertical integration, its revealed preference for processing oranges in its own facilities, and the inability of the plaintiff to purchase oranges from Sunkist at competitive prices.

Sunkist contended that its conduct was "legitimate, cooperative activity and not undertaken in an unlawful manner or for an unlawful purpose" [4, p. 495]. In addition, Sunkist contended that it was a cooperative association of "persons engaged in the production of agricultural products" within the meaning of the Capper-Volstead Act [6] and therefore could not be held for an intra-organizational conspiracy to restrain trade in violation of section 1 of the Sherman Act.

Case-Swayne argued that Sunkist was not exempt from prosecution under section 1 of the Sherman Act, because approximately 13 percent of the volume of the Sunkist organization was with local association members who were private profit making corporation and partnership packing houses not engaged in the production of fruit [4, p. 460]. These local associations contracted with growers to handle their production on a cost-plus basis. The locals then contracted with Sunkist to market their products. These arrangements with the noncooperative locals, of course, gave Sunkist control over a larger proportion of the volume of oranges marketed.

The district court granted Sunkist's motion for a directed verdict[1] on the premise that the relevant market was national in scope and that evidence was not shown of an illegal monopoly. The court of appeals reversed the directed verdict, holding that there was sufficient evidence to submit to the jury the questions of:

1. Whether the relevant product market was product oranges and the relevant geographic market Southern California-Arizona; and
2. Whether Sunkist had wrongfully exercised and intentionally attempted to monopolize in violation of section 2 of the Sherman Act[2] [4, p. 459].

In addition, the court of appeals held that the contracts with the agency associations were independent contracts for legitimate objectives of marketing and processing. In so holding, the court noted that:

---

[1] "A motion to direct a verdict is an application to the court by one of the parties for entry of judgment in its favor" [11, p. 262].

[2] Note that the court of appeals did not find that Sunkist had engaged in any of the alleged acts of monopoly—only that the evidence as a whole indicated that the case should have been submitted to a jury.

1. The agency associations did not participate in the gain or loss involved in marketing fruit through Sunkist; and
2. Sunkist was an association of producers organized under the Capper-Volstead Act and therefore "may make the necessary contracts and agreements . . . for . . . collectively processing, preparing for market, handling and marketing . . ." their products [4, p. 460].

The question of whether Sunkist, with non-grower agency association members, was an association of persons engaged in the production of agricultural products within the meaning of the Capper-Volstead Act was the sole issue in the Supreme Court appeal. The Supreme Court held that Sunkist, with non-grower members, was not a Capper-Volstead cooperative and therefore was not entitled to Capper-Volstead exemption from prosecution under section 1 of the Sherman Act. [5, L. Ed. 2d, p. 623].

In its decision, the court noted that Congress explicitly stated that a cooperative cannot seek to enlarge its market share by enlisting the membership of nonproducer organizations. Trade is restrained in this case because the nonproducer organizations are eliminated as competitors both in the grower market for produce and in the fresh and/or processed fruit market.

In so holding, the court noted that in cases where the parties to the antitrust suit are marketing cooperatives whose members are engaged in the production of agricultural products, cooperatives have been allowed to pursue their efforts to gain market control as long as predatory practices were not used to exclude other firms or producers from markets. In *Sunkist Growers, Inc. et al. v. Winckler and Smith Citrus Products Co.* [12], the court rejected an intraenterprise conspiracy contention that Sunkist had conspired with a wholly owned subsidiary and with a separate stock company owned by the Sunkist local association members. Even though Sunkist controlled about 70 percent of the California-Arizona citrus market, the court found that agreements among the three cooperative organizations were within the protection of the Capper-Volstead Act.

In cases where mergers, acquisition, or restrictive market practices involve a cooperative and a noncooperative firm, a standard of legality much closer to that applied to other firms has been applied. In *Maryland-Virginia Milk Producers Association v. U.S.* [9], the court held that a milk marketing cooperative had violated both the Sherman Act and section 7 of the Clayton Act when it attempted to exclude competing sources of milk by purchasing the largest noncooperative milk dealer in the Washington, D.C. market. Similarly, in *U.S. v. Borden Co.* [14], the court held that a price fixing conspiracy between a Capper-Volstead cooperative, milk distributors, labor unions, and others was illegal. In so holding, the court noted that the right of agricultural producers to unite under the Capper-Volstead Act ". . . cannot be deemed to authorize any combination or conspiracy with other persons in restraint of trade that these producers may see fit to devise" [14, p. 204–205].

The *Case-Swayne* decision raises a basic question as to the extent to which nonproducers can participate in the activities of a marketing cooperative and still maintain its exempt status. The court's decision provides some insight into this question, but leaves an important gray area. First, 5 percent of the Sunkist local association membership were corporate arranged, profit making, vertically integrated grower-packing houses. The court reasoned that since these organizations were owned by producers, they did not jeopardize the antitrust exempt status of Sunkist.

Does this mean that in order for a cooperative to maintain its antitrust exempt status, it must completely divorce itself of nonproducer interests? Apparently not. In its concluding statements, the court recognizes ". . . that producers who desire to organize for collective marketing might not have, at the outset, the necessary finances to do so, and might therefore seek capital from nonproducers. . ." [5, fn. 13, L. Ed. 2d, p. 628]. It notes, however, that the financial stake of such nonproducer participation does not directly enlarge the market share already possessed by the producers themselves. In contrast, the participation in Sunkist by nonproducer packing houses has precisely the effect of increasing the market share of Sunkist. Therefore, the most direct lesson from the *Case-Swayne* case is that *noncooperatives or nonproducer interests should not be used by marketing cooperatives as a method of increasing their market share.*[3]

A gray area which still exists after the *Sunkist* case involves the extent of nonproducer interests which can exist in a local association and yet maintain its exempt status. Would partial integration into orange growing by the nonproducer associations be sufficient to make them a producer within the meaning of the Capper-Volstead Act? The answer to this question is uncertain, but past antitrust decisions and the reasoning in the *Case-Swayne* decision suggest that the answer would depend largely upon the motive for integration. Given merely token integration, with nonproducers the main beneficiaries, the cooperative very likely would not maintain its exempt status. Thus, a livestock marketing cooperative probably would not be able to maintain exemption if a large meat packer involved in some cattle feeding became a local affiliate. In any event, it would appear that the decision severely limits cooperative use of nonproducer organizations as a means of obtaining more market control.

---

[3] It should be noted that, except to the extent that the definition of a Capper-Volstead cooperative is affected by the *Case-Swayne* decision, there does not appear to be any effect on the procedures provided for under section 2 of the Capper-Volstead Act. Neither does the *Case-Swayne* decision affect the eligibility of an association to borrow from the Bank for Cooperatives, which requires that 90 per cent of the voting control of a borrower be in the hands of producers.

Another question that remains open after the *Sunkist* case is the extent to which a cooperative can control or increase its share of the market and yet not be held to have monopolized the market in violation of section 2 of the Sherman Act. As indicated previously, the court has held that while the Capper-Volstead Act gives cooperatives the right to organize and carry out its legitimate objectives, a cooperative may still be found liable under section 2 of the Sherman Act for wrongful use of monopoly power and attempt to monopolize [4, 5, 7, 9, 12, 14]. Therefore, in the case of a section 2 violation, the standard of legality would likely be the same as that applied to cases involving noncooperative firms charged with a combination or conspiracy to monopolize [4, p. 458; 9, 14].

Violation of section 2 involves both the structural elements of monopoly and the act of monopolizing. Thus in *U.S. v. Grinnell*, the court stated that "The offense of monopoly under section 2 of the Sherman Act has two elements: (1) the possession of monopoly power in the relevant market and (2) the willful acquisiton or maintenance of that power as distinguished from growth or development as a consequence of a superior product, business acumen, or historic accident" [16, p. 570].

The proportion of the market that a firm must control to be considered to have monopoly power is not clear cut. In *U.S. v. Alcoa*, the court stated that a firm's control of over 90 percent of the market is enough to constitute a monopoly. At the same time the court stated, ". . . it is doubtful whether sixty or sixty-four percent would be enough; and certainly 33 percent is not" [15, p. 424]. In the *Alcoa* case, the combination of over 90 percent control of the relevant market with evidence that Alcoa had diligently sought to accomplish and maintain this control, through means such as the maintenance of substantial excess capacity and similar exclusionary practices, led the court to the conclusion that Alcoa had monopolized the market in violation of section 2 of the Sherman Act.

In *U.S. v. United Shoe Machinery* [17], United's control of 75 percent of the shoe machinery market, combined with a network of long term leases that strengthened its power to exclude competitors, was in violation of section 2. Similarly, in the previously mentioned *Maryland-Virginia Milk Producers* case, 86 percent control of the milk supply, combined with agreements to exclude competition, was declared illegal. These and other cases led Earl Kintner, former general counsel to and thereafter chairman of the Federal Trade Commission, to conclude that ". . . if a corporation has the power to fix prices or to exclude competition in the market in which it competes, or if it dominates roughly 75 percent of the market in which it competes, there is a good chance that a court will hold that it possesses the requisite powers for monopolization" [8, p. 100]. The *Maryland-Virginia* case and the *Borden* case indicate that a cooperative which combines about 75 percent control of the market with the power to fix price or attempts to exclude competitors might well be subject to prosecution under section 2 of the Sherman Act, notwithstanding the fact that it is a Capper-Volstead cooperative.

A court of appeals decision that has received much attention from cooperatives and their leaders is *Cape Cod Food Products v. National Cranberry Assn.* [2]. In the *Cape Cod* decision, the court stated that a cooperative may attain a monopoly ". . . to the extent of 100 percent of the market through superior skill, efficiency, superiority of product . . ." or "if it does it exclusively through marketing agreements approved under the Capper-Volstead Act" [2]. This statement should not, however, be taken as a basis for cooperative monopoly activity. First, it is not completely consistent with statements in other Supreme Court and court of appeals decisions, some of which were discussed previously in this article [4, 5, 7, 9, 12, 14]. Second, in the next breath, the court repeated what it has stated in other cases: that "It would be a violation of the law, and it would be a prohibited monopolization for a person or group of persons to seek to secure a dominant share of the market through restraint of trade which was prohibited, or through a predatory practice or through the bad faith use of otherwise legitimate devices" [2]. Third, the court used similar language with respect to superiority, skill, and efficiency when Alcoa was found guilty of monopolizing activity [15]. Cooperatives must thus, under existing laws, be very careful when it comes to monopolizing activities. It should be apparent from this discussion that the law in the monopolization area with respect to cooperatives is unsettled.

Case-Swayne Co. v. Sunkist Growers, Inc. provides marketing cooperatives with a much needed guide regarding their membership. If an association has any nonproducer member who has any voice or vote in association affairs, the Capper-Volstead Act cannot be used as a defense in a restraint of trade charge based on section 1 of the Sherman Act. In addition, the Capper-Volstead exemption cannot be relied on to protect a cooperative from charges of monopolization under section 2 of the Sherman Act.

As bargaining and consolidation of cooperatives by merger and federation become more prevalent, the extent of exclusion from antitrust prosecution which is provided by the Capper-Volstead Act will become an increasingly important issue. Also, as agriculture becomes more fully integrated, the distinction made in the *Case-Swayne* decision between producers and producer interests will become an increasingly difficult question with respect to interpretation of the Capper-Volstead Act.

THE SUPPLY FUNCTION IN AGRICULTURE REVISITED
(Joint Session AEA and AAEA)

CHAIRMAN: GLENN L. JOHNSON, MICHIGAN STATE UNIVERSITY

Positivistic Measures of Aggregate Supply Elasticities: Some New Approaches*

LUTHER G. TWEETEN AND C. LEROY QUANCE

SUPPLY elasticities indicate the speed and magnitude of output adjustments in response to changes in product price. The elasticity parameter for aggregate farm output is especially important for public policy because it measures the ability of the farming industry to adjust production to changing economic conditions continually confronting it in a dynamic economy.

Farmers have considerable latitude to substitute one commodity for another in production over a long period. Eventually, this should lead to adjustments among commodities until comparable resources are earning similar rates of return in production of each commodity. Public policies concerned with the earnings of all farm resources and total farm income must consider the aggregate response of farm output to changing economic conditions. The aggregate response of output to price depends on total resource adjustments in agriculture. Because farm resources are adjusted much more easily among farm commodities than between farm and nonfarm commodities, it follows that the aggregate supply response, which tends to determine total resource earnings in agriculture, is less than the supply response for individual commodities.

Questions we attempt to answer in this paper include: What is the magnitude of the elasticity of U.S. farm output with respect to price in the long

and short run? Is the elasticity increasing over time as the ratio of purchased to non-purchased inputs increase? And are farmers less responsive to price decreases than to price increases as fixed asset theory implies? Three positivistic approaches are used to estimate the aggregate supply elasticity. The first is a direct least squares estimate of the aggregate supply function. One advantage of this approach is that it is straight forward and does not entail problems of aggregating estimated supply parameters with associated problems of substitution and interaction among the time series and difficulty in separating the influence on output of technology and durable resources—hence, it is difficult to determine the long-run supply elasticity.

Two additional disaggregate approaches which circumvent at least some problems of intercorrelation are also used to estimate the supply elasticity. One involves direct least squares estimates of the separate yield and basic production unit components of (a) crops and (b) livestock. These components are then aggregated to form the elasticity of total supply. The second disaggregate approach is to compute the elasticity of supply from production elasticities and demand elasticities for eight farm inputs. These latter two approaches add to our knowledge of component sources of aggregate supply response.

Direct Least Squares Estimates of the Aggregate Supply Function

Estimates of the aggregate U.S. supply function of farm products presented in Table 1 were obtained by regressing output on relative prices, productive assets, and technology as defined below:

O^t: The dependent variable, output, measured as the index of aggregate farm output (1957–59 = 100) [14]. In one equation, lagged output, O^{t-1}, is used as an independent variable.

$P_r/P_p{}^{t-1}$: The lagged index of the ratio of prices received by farmers for crops and livestock to prices paid by farmers for items used in production [3, 12]. When $P_r/P_p{}^{t-1}$ is for a specified period or for years of declining or increasing relative prices, it is the actual observation for the specified years but has a zero value for other years in the period observed (1957–59 = 100).

Sp^t: The beginning of the year stock of productive farm assets, including real estate, machinery, feed, livestock, and cash held for productive purposes; measured in millions of 1957–59 dollars [12, 13].

T: Productivity index; the ratio of farm output to all farm production inputs in the current year (1957–59 = 100) [12, 13]. This productivity variable reflects changes in management and technology as well as fluctuations in productivity induced by weather.

Table 1. Supply functions for aggregate farm output, *O*, estimated by least squares with annual U.S. data for specified time periods; coefficients, standard errors (in parentheses), and related statistics

Equation	Time period	R^2 d'[b]	Constant	P_r/P_p^{t-1}	S_p^t	T	O^{t-1}
1	1921–66[a]	0.993 .871	−30.70	0.0693 (.0194)	0.2167 (.0965)	1.0449 (.0559)	
2	1921–41	.890 .968	−69.23	.05326 (.0327)	.6366 (.4441)	1.1395 (.1007)	
3	1948–66	.982 .465	−57.23	.1380 (.0811)	.4901 (.2365)	.9587 (.0862)	
4	1921–66	.993 .932	−26.41	*1921–32* .0738 (.0179) *1933–47* .0628 (.0175) *1948–66* .0695 (.0165)	.0969 (.1158)	1.1134 (.0655)	
5 (Increasing prices)	1921–66	.992 1.1108	−45.54	.1066 (.0267)	.4264 (.1312)	.9425 (.0755)	
6 (Decreasing prices)	1921–66	.996 .962	−19.00	.0502 (.0173)	−.0002 (.0974)	1.1521 (.0561)	
7	1921–66	.993 1.442	−18.48	*Increasing prices* .0554 (.0154) *Decreasing prices* .0538 (.0163)		.9667 (.0642)	.1776 (.0563)

[a] Observations for the years 1942–47 are omitted.

[b] The Durbin-Watson autocorrelation statistic d'. The test for autocorrelation is inconclusive in equation 2, 5, and 7; and is significant at the .05 probability level (two-tailed) in the remaining equations. Computing a first order autoregressive scheme was precluded by lack of time.

Two approaches were used to test for differences in supply structure over time and between increasing and decreasing price phases. One was to estimate separate equations for component periods and use an F test to determine if the structure was unchanged. Another approach was to divide the price variable into component periods but leave other variables unchanged in the single least squares equation for the entire period.

In equation 1 (Table 1), output is expressed as a function of relative prices, the stock of productive assets, and productivity with observations over the

1921–1966 period, excluding 1942–47. The variables account for a high proportion of the variation in output and in all instances, the hypothesis that the respective coefficients are equal to zero is rejected at the 0.05 probability level.

The same specification is repeated in the next two equations with equation 2 estimated with 1921–41 data and equation 3 with 1948–66 data. Standard errors increase markedly compared with those in equation 1 and statistically, only the coefficients of T in the two equations are consistently different from zero. An F value, calculated to test the hypothesis that the respective coefficients in the two equations were equal, was nearly one. Hence, there is no basis to conclude that the structure of supply changed between the postwar and prewar periods.

The limited observations in the equations segmented by time periods poses a problem. To conserve degrees of freedom and to obtain a more precise test of possible changes in the response of output to price, equation 1 was reestimated with the price series divided into three segments. The first price variable contained actual observations for the 1921–32 period, zeros elsewhere. The second contained actual price observations for the 1933–47 period, zeros elsewhere. And the same procedure was used to construct a third variable for price in the 1948–66 period. The resulting specification in equation 4 explained no more of the variance than that in equation 1. The price coefficients were significantly different from zero at the 0.01 level, but a statistical test is hardly needed to conclude that the coefficients of the segmented price variables do not differ significantly. In short, there is little basis from equations 1–4 to conclude that the response of output to price has increased over time.

Equations 5, 6, and 7 are included to determine whether the supply structure differs between years of increasing and decreasing prices. The coefficients in equation 5, estimated with 23 observations from years of increasing prices in the 1921–66 period, are significantly different from zero at the 0.01 probability level. The coefficients of the price and productive assets variable in equation 6, estimated with 23 observations from the years of decreasing prices in the 1921–66 period are smaller in magnitude and statistical significance than their counterparts in equation 5. An F test was used to evaluate the hypothesis that the structure of supply was unchanged between increasing and decreasing price years. The hypothesis that the respective coefficients in the two equations were equal is rejected at the 0.10 level but not at the 0.05 probability level. Since the probability was small (less than 10 percent) of obtaining an F ratio so large if the structure was identical for increasing and decreasing prices, some support is provided for the role of fixed asset theory in explaining aggregate supply response.

Equation 7 expresses farm output as a function of productivity, lagged output, one price variable for decreasing prices and another price variable for increasing prices. Coefficients of all variables differ significantly from zero at the 0.01 probability level But coefficients of the segmented price variables are nearly identical, giving no basis for concluding that the response of farm output to price differs from rising and falling prices.

Several variants of the equations in Table 1 were estimated. One was to divide lagged output into segments and leave price and productivity in their original form for the 1921–66 period. Dividing lagged output into two variables associated respectively with increasing and decreasing prices permitted evaluating the hypothesis that the rate of adjustment of output to the two variables differed between price phases. Segmenting lagged output into three variables associated respectively with the 1921–32, 1933–47, and 1948–66 periods as with price in equation 4 provided a test of the hypothesis that the adjustment rates differed among these periods. Similarity of adjustment rates provided no support for either of the two hypotheses.

Most equations in Table 1 were also estimated with data coded into logarithms. The R^2's of the logarithm equations were generally below those for the equations in Table 1. Also, the equations estimated in logarithms provided no support for the hypothesis that the elasticity of supply is increasing over time or that the elasticity of supply is greater for increasing prices than for decreasing prices.

Elasticity of supply

We now examine supply elasticities estimated from equations in Table 1. The rising proportion of farm inputs comprised of highly productive and flexible purchased inputs including fertilizers, pesticides, and improved feed supplements suggests that the supply elasticity rises over time. On the other hand, farming is becoming more specialized. If an increasing proportion of farm output is produced by highly specialized broiler, pork, beef, or feed producers who continue to operate at full capacity over a considerable range of price ratios, supply elasticity will fall. Furthermore, the elasticity of supply $(\partial O/\partial P)\ (P/O)$ may fall because the marginal coefficient $\partial O/\partial P$ derived from equations such as those in Table 1, even if increasing over time, is more than offset by a falling P/O ratio. The ratio P/O has in fact fallen as output expanded and prices declined. This is expected with improved resource productivity—more is produced at a given price while maintaining the rate of return on resources.

Prices also influence output in the short run through the stock of productive assets, Sp, and this impact is accounted for in the Table 2 estimates.[1]

---

[1] The stock of production assets was regressed in linear form on time, $P_r/P_p{}^{t-1}$, and lagged production assets with the following results:

$$(6.)\quad S_p{}^t = \underset{}{0.73} + \underset{(0.025)}{0.072}\ (\text{Time}) + \underset{(0.009)}{0.020}\ (P_r/P_p)^{t-1} + \underset{(0.036)}{0.935}\ (S_p{}^{t-1})$$

with $R^2 = 0.990$. Standard errors are in parentheses. From this equation, the elasticity of $S_p{}^t$ with respect to $P_r/P_p{}^{t-1}$, E_{sp}, was 0.228 for 1921–66; 0.598 for 1921–41; and 0.481 for 1948–66.

The 0.155 supply elasticity computed from equation 1 is the best single estimate of the short-run supply elasticity for the entire period. The results provide no clear mandate for a higher elasticity in the postwar period nor in increasing price phases; hence, 0.155 may be the best estimate for any of these conditions. Nevertheless, supply elasticities are also shown for increasing and decreasing prices and for the postwar and prewar periods. Equations 5 and 6 indicate that the short-run supply elasticity could be 0.17 for price increases and 0.07 for price decreases. Estimates from equations 2 and 3 indicate that the short-run elasticity could be 0.08 in the prewar period and 0.16 in the postwar period. But elasticities computed from equation 1 contradicted this conclusion in that a declining P/O ratio is multiplied by a fixed marginal coefficient 0.0693. Additional evidence from other techniques are examined before a final interpretation is made of the short-run supply elasticity.

Table 2. Estimates of aggregate short-run supply elasticity of U.S. farm output for specified periods[a]

Period	Aggregate supply elasticity (Short run)
1921–1966	
Without regard to direction of price movement (Equation 1)	0.155
Price increases (Equation 5)	.169
Price decreases (Equation 6)	.069
1921–1941	
(Equation 1)	.132
(Equation 2)	.080
1948-1966	
(Equation 1)	.085
(Equation 3)	.162

[a] Elasticities computed from equations in Table 1 at the means of the respective periods, as indicated.

One hypothesis is that the equations in Table 1 fail to provide strong support for rising elasticities over time because the decreasing prices and attendant low elasticities occurred in the postwar period. Although concentration of decreasing or increasing prices in one of the segmented time periods could cause confounding of the two major hypotheses tested—that is not

---

And the adjustment coefficient for productive assets g_{sp} is $1-0.935=0.065$. In adjusting the aggregate supply elasticity for the impact of P_r/P_p on S_p, the short-run elasticity is equal to the elasticity of supply with respect to price derived from equations in table 1 plus the elasticity of output with respect to productive assets derived from equations in table 1 multiplied by the elasticity of productive assets with respect to P_r/P_p, E_{sp}. The long-run aggregate supply elasticity is obtained in a similar manner except that the elasticity of productive assets with respect to P_r/P_p is divided by the adjustment coefficient for productive assets, g_{sp}, in the above calculations.

the case in Table 1. Excluding 1942–47, of the 19 years of increasing prices in the 1921–66 period, 11 occurred in the 1921–41 period and 8 in the 1948–66 period. And of the 21 decreasing prices, 10 occurred in the 1921–41 period and 11 in the 1948–66 period.

The long-run supply elasticity from all equations except 7 in Table 1 can be computed by considering the long-run impact of prices on *Sp* and *T*. Productivity, *T*, regressed on prices and a time variable revealed no association between prices and *T*. Thus, the impact of prices on output through *T* can be ignored. The influence of prices on output through *Sp* is found from a regression of *Sp* on prices and other variables as indicated previously in footnote 1. The long-run supply elasticity is estimated at 0.31 both for the 1921–41 (equation 2) and for the 1948–66 (equation 3) periods. Equation 1 indicates a 0.19 long-run supply elasticity for the 1921–66 period. The long-run elasticity computed from equation 7 is also in line with this estimate. These estimates are considerably below the 0.6 long-run supply elasticity estimated by Heady and Tweeten in 1963 [5, p. 435]. The long-run supply elasticities computed from the equations in Table 1 are also low when compared with results from the disaggregate approach presented later. We conclude that high correlation between productive assets, *Sp*, productivity, *T*, and, in the case of equation 7, lagged output, biases the long-run supply elasticity toward zero.

Aggregate Supply Elasticity Computed From Crop and Livestock Components

Estimates in Table 3 of the elasticity of crop acreage, yield, and other components of aggregate supply with respect to price are taken from previous studies. In these studies, the coefficients of livestock and crop supply functions were computed by least squares from time series. The components are weighted and combined to form an estimate of the elasticity of aggregate supply. The underlying data were not adequate for separating the elasticities for increasing and decreasing prices and for postwar and prewar periods.

For all crops, the acreage response to price is quite low in both the short and long run (Table 3). But yield response is considerable in the long run. The total elasticity of farm crop production with respect to prices received by farmers is the acreage elasticity plus the yield elasticity corrected for the negative effect of higher acreage on yields as production moves to lower yielding land.

The production period for livestock such as poultry and hogs is comparatively short, hence, animal units of livestock show a greater response than acreage to higher farm prices (Table 3). While output per animal unit is more responsive to price than is the number of animal units in the short run, the reverse is true in the long run. That is, there is greater potential for expanding livestock production by increasing the number of animal units than by

Table 3. **Estimated aggregate supply elasticity of farm output, with crop and livestock components**[a]

Item	Elasticities	
	Short run (2 years)	Long run (Many years)
Crops[b]	0.17	1.56
Acreage	.04	.10
Yield per acre	.15	1.50
Livestock[c]	.38	2.90
Animal units (stock)	.12	1.80
Yield per animal unit	.26	1.10
Aggregate supply elasticity[d]	.25	1.79

[a] Data interpreted from [1; 5, Ch. 16].

[b] The elasticity of crop production C with respect to farm price P is E_{CP}. Given the elasticity of acreage with respect to price E_{AP}, the elasticity of yield with respect to price E_{YP}, and the elasticity of yield with respect to acreage $E_{YA} = -.4$, then $E_{CP} = E_{YP} + E_{AP}(1 + E_{YA})$.

[c] Computed as in above footnote, with the elasticity of livestock yield with respect to animal units E_{YA} equal to zero.

[d] Computed by the formula: $E_{OP} = E_{CP}\ C/O + E_{LP}\ L/O + E_{LC}\ E_{CP}\ L/O$ where O is total farm output, C is crop output, L is livestock output, and P is the index of prices received by farmers. E_{OP} is the supply elasticity of O with respect to P. Other elasticities E_{ij} are interpreted accordingly. E_{LC} is assumed to be -0.4 in the short run and -0.6 in the long run.

increasing yield per animal unit over an extended period. Empirical results do not show that increasing the number of animal units depresses the yield per unit; hence, the supply elasticity of total livestock output is the simple sum of the unit and yield components.

The total elasticity of farm output with respect to product price is a weighted sum of the livestock and crop components. There are opportunities to substitute livestock for crops by feeding. We attempt to include this interaction by a term E_{LC} which is the elasticity of livestock output with respect to crop output (see footnote d, Table 3). With a given supply of crops, an increase of livestock means less crops for final sales to consumers—hence, E_{LC} is negative. The elasticity of total supply computed from data in Table 3 is 0.25 in approximately 2 years and is 1.79 in many years. This implies that a sustained 10-percent increase in prices received by farmers raises farm output 2.5 percent in 2 years and 17.9 percent in many years. The reliability of some of the estimates such as E_{LC} in Table 3 is low, and the elasticities must accordingly be interpreted with caution.

Aggregate Elasticity of Supply Computed from Farm Input Components

Agricultural economists place much emphasis on factor markets as the roots of the supply adjustment problem in agriculture (see, for example, Hathaway [4], Heady and Tweeten [5], and Glenn Johnson [7]). And in stratifying capital inputs into groups with similar characteristics with respect to durability, degree of specialization, and source of supply, Quance found that expendables are adjusted toward rates of use which equate relevant *ex post* MVPs or lifetime earnings with original acquisition costs more rapidly than durables, farm-produced durables more rapidly than nonfarm-produced durables, nonfarm-produced expendables more rapidly than farm-produced expendables, and inputs which are unspecialized to the farm sector more rapidly than specialized inputs [8]. These differing adjustment rates for farm inputs have important implications for aggregate supply elasticity. Before drawing conclusions concerning the magnitude of aggregate supply elasticity, a further estimate relating the elasticity of supply to the adjustment of specified input categories is obtained.

This estimate of supply elasticity is determined from the elasticities of production and the elasticities of input demand with respect to prices received by farmers. In other words, output is a function of the productivity of an input and its level of use. And the level of use is a function of farm product prices.

From the estimates of production elasticities and elasticities of demand for specified inputs in Table 4, the contribution of an input i to aggregate supply elasticity is obtained by multiplying the elasticity of production, E_{Oi}, by the elasticity of demand, E_{ip}, for input i. The total price elasticity of supply of farm output E_{CP} is then

Table 4. Estimated elasticities of production, input demand, and product supply for U.S. agriculture[a]

Input	Elasticity of production	Elasticity of demand				Contribution to aggregate supply elasticity	
		Own-price		Product price			
		SR[b]	LR[b]	SR	LR	SR	LR
Fertilizer and lime	0.06	−0.6	−1.8	0.5	2.4	0.030	0.144
Machinery operating expenses	.11	−1.0	−1.5	.5	2.5	.055	.275
Feed, seed, and livestock	.09	− .8	−1.5	.7	2.0	.063	.180
Miscellaneous current operating expenses	.09	− .3	− .5	.3	2.5	.027	.225
Crop and livestock inventories	.04	− .2	−1.0	.2	2.5	.008	.100
Machinery inventory	.10	− .2	−1.0	.2	2.6	.020	.260
Labor	.25	− .1	− .5	.1	1.0	.025	.250
Real estate	.28	[c]	[c]	.1	.3	.028	.084
Total elasticity	1.02					0.256	1.518

[a] Data based on [5], [9], [10], and [11].

[b] SR refers to a short run of 2 years; LR refers to a long run of many years.

[c] Nearly zero.

Based on these estimates, a once-for-all *decrease* of 10 percent in prices received by farmers would decrease output 1 percent in 2 years and 8 percent after many years. But a once-for-all *increase* of 10 percent in prices received by farmers would increase farm output 1.5 percent in 2 years and 15 percent after many years. The relative difference is less between the short-run elasticities for the two price phases than between the long-run elasticities. This is because the operating inputs which generate the shortrun response are consumed with little carryover of service—hence, give rise to little resource fixity and to greater symmetry in response to price. The long-run elasticity, which depends on durable inputs, is more heavily influenced by resource fixity and this is reflected in the considerable differences in long-run elasticities for increasing and decreasing prices.

The Representative Farm Approach to Estimation of Supply Response

JERRY A. SHARPLES

IN this paper I discuss the role that representative farms have played in the estimation of *aggregate* supply response, and I speculate on the future role of representative farms in *aggregate* analyses. I do not discuss the valuable contribution or the problems associated with the use of representative farms in *firm* analyses *per se.*

Many empirical techniques can be used to estimate aggregate supply response. They include regression, spatial equilibrium, mathematical programming, and less formal techniques. However, the representative farm approach has been by far the most popular research approach used for both firm and aggregate supply response analysis during the 1960's. True, other techniques were used, but no model in the history of production economics has received as much widespread research support in the form of research funds and professional manpower. I am referring to the regional adjustment studies and the associated state studies. In all these studies representative farms were used to estimate aggregate supply response. Since most of the regional adjustment studies have been completed, it is time to evaluate how well this approach to supply response has worked, and to speculate about where we should go from here in aggregate supply analysis.

Representative Farms and Aggregate Supply Response—Last Ten Years

The history of supply response research and the role played by representative farms are well documented.[1] I would like to break into the historical chain of events at about the late 1950's. At that time there was discussion about a supply response model that was based on the aggregation of representative farm results—the model that later became the foundation of the regional adjustment study research. This model had five major components. These were, following Barker and Stanton [1, p. 701]: (1) stratify all farms within a region into homogeneous groups, (2) define a representative farm for each stratum, (3) derive supply functions for each farm, (4) aggregate the supply functions, and (5) remove the model's simplifying assumptions and adjust the results accordingly in order to make predictions or prescriptions. I can find no label in the literature for

---

[1] See Barker and Stanton [1], Nerlove and Bachman [7], the book on agricultural supply functions edited by Heady and others [6], and the proceedings papers and discussions of the use of representative farms in agricultural economics, at the summer, 1963, AFEA meetings [3], [5], [9].

JERRY A. SHARPLES *is an agricultural economist with the Economic Research Service, USDA.*

this model so I will call it a "representative farm aggregation" model (RFA model).[2]

The RFA model had an intuitive appeal. First, it seemed to provide the missing research link between the firm and the industry—the micro and the aggregate. The impact of a change in a variable could be traced from the farm where the production decisions are made, up to the industry where policy decisions are made. A model that could predict aggregate response via the micro route appeared to be a powerful tool.

Second, the normative characteristics of the RFA model would allow its use for studying conditions that had not occurred in the past. This model could overcome the great limitation of regression analysis.

The RFA model was not new in the late 1950's, but two research innovations caused renewed interest in the model—linear programming and electronic computers. It would have been a formidable task to derive supply functions for many representative farms by hand, using conventional budgeting techniques. But LP and computers overcame this problem. Thus, the profession got excited about the potential of the RFA model as a research tool. It appeared that even though many theoretical and technical problems were anticipated, we were surely at the dawn of a new era in understanding aggregate supply response.

In 1958 the first of six regional adjustment studies—the Lake States dairy study—was initiated. Over the next five years similar adjustment studies were started in the Northeast, South, Corn Belt, Great Plains, and West. The RFA model was the foundation for each of the six regional studies. The Lake States dairy study was completed in 1963.[3] The last of the regional adjustment studies will probably be completed by 1969.

These studies were cooperative ventures by the State agricultural experiment stations and the Farm Production Economics Division of the Economic Research Service, U.S. Department of Agriculture. The primary objectives of all the regional adjustment studies were (1) to estimate adjustments needed in resource allocation on farms to maximize profits, (2) to estimate regional supply response, and (3) to determine an equilibrium supply-demand condition for a region and then for individual farms. The U.S. Department of Agriculture had special interest in short and intermediate-run regional analyses and the State experiment stations had special interest in the farm, sub-State and State analyses.

The great expectations that the profession had for the RFA model as used in the regional adjustment studies is shown by the large expenditure of research resources we were willing to invest. A rough measure of this research support is the number of published reports and the number of M.S. and Ph.D. theses connected to the regional adjustment studies. For example, from the Southern (S-42) and Corn Belt (NC-54) adjustment studies combined came over 80 research publications, 40 M.S. theses, and 20 Ph.D. theses. Many of the theses are included in the count of publications. Additional publications and theses came—and are still coming—from the other adjustment studies but a tally of them is not available. The profession will, for many years, be feeling the impact of having a large number of their production economists trained via the regional adjustment studies.

---

[2] I use "RFA model" to refer to a model where (a) the unit of analysis is obviously the firm; i.e., the restrictions and alternative activities in the model reflect a firm's restrictions and alternatives, and (b) the primary objective is the estimation of aggregate supply response.

[3] The Lake States results are summarized in [12]. Examples of other regional results are [4], [8], and [10].

Much has been gained from the regional adjustment studies. First, but possibly not foremost, were the representative farm adjustment results and the regional results. Second, a data base (budgets, representative farm data, and other quantitive data) was established that is currently being utilized and updated in other research projects. Third, these studies provided graduate training, as noted above, and technical training as well. Many in the profession got their first taste of mathematical programming and electronic data processing via the regional adjustment studies.

And fourth, we learned that the problems connected with the RFA model were more devastating than we had first imagined. The aggregate regional analysis—the justification for having regional projects—was disappointing. I think that the disappointment, however, was caused more by the original great expectations than by actual performance.

Problems with the RFA model

Several writers have dwelled on the problems associated with the RFA model as used in the regional adjustment studies.[4] The problems most difficult to overcome can be grouped into five categories: (1) interdependence or externalities, (2) change in farm size, (3) unrealistic firm-level assumptions, (4) the selection of representative farms, and (5) mechanical problems.

Interdependence or externalities.—In the RFA model used in the regional adjustment studies, aggregate supply response is obtained by the summation of weighted representative farm supply functions. The individual farm's input costs and physical transformation rates are assumed to remain constant at all levels of aggregate production. But we know that the aggregate level of production has a major impact on input prices which in turn affects each farm's supply function. The impact is greater as larger regions are analyzed. If we were studying supply response of corn and our analysis were limited to Michigan, a 20-percent change in corn production in Michigan would not have a major impact on input prices, but if the Corn Belt were our area of analysis, a change in corn production of 20-percent would alter input prices considerably.

---

[4] For example, see Barker and Stanton [1], Sharples, Miller, and Day [11], or Brokken [2].

Attempts are now being made to overcome this problem by putting all representative farms into one programming model. The major inputs can then be limited on a regional or sub-regional level, or they can enter the matrix as a regional stepped supply function. The representative farms could then compete for inputs such as beef feeders, feed, and labor. However, this approach creates about as many problems as it solves. How do you define the regional or sub-regional supply of, say, beef feeders? Are you willing to live with a solution that maximizes area profits instead of firm profits? Also, the size of the computational problem becomes a major factor in limiting the number of representative farms.

Change in farm size.—A major factor associated with aggregate supply response is the changing size of the farm. In the RFA model it is very difficult to evaluate the aggregate impact of allowing representative farms to buy or rent additional land. There is no way to insure that purchased land equals sold land or that land rented in equals land rented out. In an attempt at overcoming this problem, several studies projected the distribution of farms by size to the target date of the study. The representative farms could then be aggregated using projected aggregation coefficients. But these attempts do not show which farms would change size or how the purchase or rental of additional land would compete with alternative farm uses of capital.

Unrealistic firm-level assumptions.—Many of the assumptions of the RFA model can be grouped under this problem heading. These include: Farmers are profit maximizers, farmers have no enterprise preferences, farmers have perfect knowledge of their alternatives, uncertainty does not enter into the choice criteria, and so on. These assumptions pertain to the individual representative farms but they have profound aggregate implications. Alternative assumptions could be examined. For example, a model that minimizes the cost of obtaining an income goal may be appropriate. Or it could be assumed that only those enterprises currently on a farm would be included in the model; i.e., livestock enterprises would not be alternatives on a representative cash grain farm.

Selection of representative farms.—The selection of representative farms and the associated problem of aggregation error have probably been the subject of the most thorough and diligent research of any of the problems listed above. These studies have shown that the number of representative farms needed to eliminate aggregation error approximates a geometric function of the complexity of the model. As more restraints and activities are defined, many more representative farms are needed. Thus one can only strive to minimize aggregation error—not eliminate it.

These studies have also shown that the traditional methods of stratifying farms—by farm size, soil type, or farm type—may lead to a set of representative farms all of which have about the same optimum organization. Recognition of differences in institutional restrictions, motivations, preferences, ability, and other human factors need to be built into the specification and stratification schemes.

Mechanical problems.—A few words need to be addressed to the purely mechanical problems associated with a model that is used to estimate aggregate supply response by summing representative farm supply functions. Only a dedicated Ph.D. candidate would have the incentive to assemble all the budgets and restraints necessary to build a reasonably rigorous model. And once the budgets and restraints are defined, the matrices are complete, and the computing is underway, a second mechanical problem arises: How will one analyze all the computer output. It takes great skill to keep from being buried in computer print-out. These technical problems cause a researcher to think twice about making any improvements in the RFA type of model that would lead to more representative farms or more activities and restrictions. Also, as one tries to build more realism into the model, he risks making the model so complicated that he cannot readily trace the logical connectives between a change in an instrument variable and a resulting change in production. A model's results are of little value if they are not accompanied by a statement explaining the causes of changes.

Future Role of Representative Farms in Aggregate Supply Response Research

This brings us up to date. We know that the RFA model as used in the regional adjustment studies has serious limitations—as do all models—and that currently there is some research endeavor to better understand the limitations. But where do we go from here in aggregate supply response analysis? What role should representative farms play in future supply response research? In order to address these questions, we need to differentiate between short-run and long-run supply response.

I do not expect the RFA model to contribute much more to expanding our knowledge of intermediate and long-run aggregate supply response. Two considerations led me to this conclusion. First, the coefficients in the RFA model reflect an assumed level of technology, an assumed institutional structure, and an assumed size of farm. Given these assumptions the RFA model focuses on profit maximization. This model has empirical relevance. But the most dynamic ingredient affecting supply response is the changing structure of agriculture—changing technology and the changing institutional framework within which agriculture functions. Representative farm models look at only one point in the whole spectrum of structural change. A more appropriate model would be one that focuses more on structural changes and less on profit maximization and movements toward equilibrium.

Second, the representative farm becomes much more difficult to define as economic time (and calendar time) becomes longer. Production coefficients, resource ratios, the objective function, and other farm characteristics are usually based on existing farms. Adjustments can be made in the parameters for some assumed increase in efficiency. But the present structure of agriculture pervades the data. When current data are used for describing a representative farm, a structure is assumed for the credit market, the input markets, the product market, Government policy, and so on. If one were to define representative farms for some point in future time, he would have to speculate on the whole structure of agriculture at that point in time before he could develop his coefficients. Because of the dynamics of agriculture, the longer the economic time period, the harder it is to specify characteristics of individual farms.

I must admit that I have no better model to put forth. Besides, that is outside the realm of my assigned topic. However, I think that we should put relatively more effort into intermediate- and long-run aggregate supply response research using aggregate data and aggregate relationships.

A conditionally normative representative farm approach to aggregate supply response is still intuitively appealing for certain types of short-run questions. For example, we may wish to analyze a 1-year response of farmers to a change in Government policy relating to diversion of wheat allotment acres. What aggregate changes would take place in wheat production, production of other crops, resource use, and farm income? In order to answer these questions adequately one must look at aggregate data and aggregate relationships, but one can get valuable insights into the nature and magnitude of the aggregate relationships by examining the effect of the policy change on several well chosen representative farms. Also in the short run (both in terms of short-run economic time and in terms of 1–3 years calendar time) technological and institutional change are much more predictable than in the longer run. Thus, the representative farm identification problem is less difficult to handle than in the long-run analysis. We can estimate production coefficients, resource ratios, and how many farms there are with various characteristics assuming the current structure of agriculture.

Up to now there has been virtually no use of representative farms for analyzing short-run aggregate supply response. The reasons are twofold: (1) the primary objective of State or regional supply response studies has been to analyze State or regional adjustment implied under normative equilibrium conditions. This objective necessarily implied a longer run model; and (2) it took a long time to collect data, define representative farms, compute, aggregate, and analyze the results. There was always the fear of finishing the study after the study projection period had passed. So projection dates had to be at least 5 years beyond the starting date of the study, or one might end up projecting to a time period that had already passed.

In order to use representative farms as an aid in short-run aggregate supply analysis, we will need to change our concepts of the role of representative farms in aggregate analyses. First, new ways will need to be developed for linking firm response to aggregate response. A simple horizontal summation of weighted representative farm supply functions has not proven satisfactory. Second, the model will have to be simpler—not more complex—than we envisioned in the past. Data handling, computing, and analysis of results will have to be streamlined, so that the research can be done quickly. For short-run analyses, timeliness of results is vital. In order to be timely, the model must contain relatively few representative farms—more in the nature of five to ten than 100-400 as in the regional adjustment studies. Experience with the adjustment studies showed that the major economic relationships—those relationships that the researchers were trying to isolate—did not differ greatly over the 100–400 representative farms. Most of these relationships could have been isolated by some parametric resource and price programming on fewer representative farms.

As an example of how this model might work, consider the following: Suppose we wanted to analyze how an increase in price support rates in a Government feed grain program would affect Iowa farmers. In order to adequately answer this question we would need to estimate changes in production, resource use and income at the State level and also give some description of which farmers would be affected. There are considerable data available at the State level to give a rough indication of the magnitude of change. Historical data series at the State level could give some indication of farmers' willingness to adjust their cropping patterns in the past to changes in instrument variables. Several representative farms in Iowa could also be analyzed to see how increased corn price supports would affect optimum production, resource allocation and income at the firm level. Information gained at the firm level could be used as an aid in adjusting the aggregate estimates.

I am admittedly vague and sketchy about the linkage between the micro case-farm type of analysis and the aggregate analysis. All I wish to point out is that one can gain insights from a limited firm analysis that is useful for understanding short-run supply response at the aggregate level. We need not ignore this micro information just because it cannot be plugged into a neat mathematical aggregation formula. This type of short-run analysis is currently being tested by the Aggregate Production Analysis Team in the Farm Production Economics Division of ERS.

Conclusions

Barker and Stanton observed in 1965 that ". . . we are still a long way from developing usable estimates of national or regional supply from individual farm data. Is it realistic to hope to use individual farm data in estimating agricultural supply? In the mid-60's the answers are not yet clear. . . . The logic of building from the bottom up still seems to outweigh all the practical problems of data collection, programming and aggregation" [1, p. 712].

Over 3 years have passed since this observation was made. Much research has gone into the "practical problems." Now we better understand these problems but they are no less formidable. The evidence is mounting that the RFA model may not play a major role in future research of intermediate and long-run aggregate supply response. The RFA model did not turn out to provide the big research breakthrough that we had originally hoped.

The representative farm can play a potentially important role in short-run aggregate supply response. Knowledge of the potential economic impact of a change in an instrument variable on a farmer's income and organization is very valuable. However, the linkage between the firm and the aggregate may by necessity be an informal one.

Nerlove and Bachman in 1960 concluded their review of supply response research with the observation that "there is a need for a combination of empirical approaches to the supply problem at all levels of aggregation between firm and industry" [7, p. 533]. During the 1960's we have been preoccupied with one empirical approach—the RFA model. Supply response is better understood by more professionals because of the extensive use of the RFA model. But the profession paid a high price by not having a more diversified approach to supply response research.

A shift in emphasis is overdue. In terms of better understanding and more accurately quantifying aggregate supply response, I think the payoff will be small from future use of the RFA model. We do not need another round of regional adjustment studies using the RFA model. What we do need is to further explore less cumbersome models that identify and better utilize stable aggregate relationships. We also need to further explore the heart of intermediate and long-run aggregate supply response—technological and institutional change.

Discussion: The Supply Function in Agriculture Revisited

JAMES H. WHITE

I will comment briefly on the Quance-Tweeten and Sharples papers and then consider some concepts of agricultural supply and problems involved in estimating supply functions for agricultural products. Some of my remarks will be directed toward the degree to which we have been conscious of these problems and to possible reasons for not taking them into consideration in the analytical models employed in studies relating to agricultural supply. We should be cautious of making final judgments on the ultimate value of our research efforts in estimating agricultural output. Agriculture is a dynamic industry and to determine exactly what it will look like at any point in the future is not possible.

The stated objective of the Quance-Tweeten paper was to develop posi-

---

JAMES H. WHITE *is professor of agricultural economics, University of Arkansas.*

tivistic measures of aggregate agricultural output elasticities. They visualized that knowledge of the aggregate output response to changes in economic conditions would be helpful to those responsible for . . . "Public policies concerned with the earnings of all farm products and total farm income . . ." Estimates of the aggregate supply function and associated elasticities were made, using three approaches: (1) direct least squares, (2) separate yields and production unit components for crops and livestock, and (3) separate input contributions to total agricultural output. There was a tone of disappointment by the authors in the results of their analysis. They stated that it is difficult to give a precise answer to a policy maker who wishes to know the response of output to price but made concluding statements based on their judgement of the reliability of the data and the methodology. This is not necessarily bad. The position in which most of us find ourselves after any research effort is something short of complete knowledge of all the relevant variables and how they relate to each other and to the problem under consideration. A student of mine once remarked that if we publish only that which is statistically significant at the three or five percent level of probability, we would have a small printing bill.

Although estimates of aggregate agricultural output elasticities may be useful for some purposes, they are "too aggregate" for making inferences to lower levels of aggregation. It is not possible to separate the impact of price changes by regions, by type of farm, by commodity or by the magnitude of the various inputs used in production. However, the results obtained by Quance and Tweeten possibly could be made more useful by including in the paper more interpretation of the results as they indicated the need for doing.

Sharples, as well as others [1], has done an excellent job in discussing the role representative farms have played in estimating aggregate supply response. Nothing is to be gained by heaping criticism on the approaches that have been taken in supply studies. Virtually all of the problems encountered have long been recognized and were re-emphasized by Plaxico and others [2] before most of the recent supply studies were initiated. Possibly too much was expected of the models we were using and too little effort was made in developing meaningful coefficients.

The prime reasons we committed ourselves to the representative firm approach for studying aggregate supply and/or output response in agriculture were because Alfred Marshall legitimized the approach and it has been paramount in the training of most agricultural economists. I am of the opinion that the inclination for economists to continue using this approach has its genesis in their formal training where emphasis was placed on profit motivated static economic theory of the firm and its linkage to the industry. Then too, the tools at our disposal—linear programming, spatial equilibrium analysis, regression and others—were thought to be potent tools for quantifying input-output relationships of the firm. Had we taken a course that would have led to relating the motives of managers, their age distribution, their equity position and other less quantifiable subjective aspects of the firm and firm-household relationships of the farm to output response, we would have been banished from the profession. As viewed by some, the results from such an approach probably would have been no more useful than the results obtained by the representative farm approach. In view of the above it should come as no surprise to anyone that agricultural economists took the representative farm approach to the study of aggregate supply.

The many facets of supply may be the source of some of the difficulty and confusion economists have encountered in estimating supply and using supply estimates foreign to the purpose for which they were developed. Evidenced by the two papers presented here today, estimates of agricultural supply can relate to estimating the response of total agricultural output of a nation, or to the response in output of a single product for a given producing unit to changes in product prices. Supply studies can also relate to the classical supply relation that refers to how the quantity offered for sale varies as its price varies relative to other product prices for some given time period and level of technology. Estimates of supply may refer to what Cochrane [3] calls an output response relation describing what will happen to the commodity offered for sale when the time period and technology are not held constant. Supply estimates can relate to static or dynamic situations; short-, intermediate- or long-run time periods; commodity or aggregate agricultural output; national policy formulation or guidance to farmers; single- or multi-product firms; a farm or a region; and others. A step toward avoiding some of the difficulties we have encountered in supply studies is to explicitly specify the purpose for which the supply estimates are made, the assumptions, the source and reliability of the data, and methodology compatible with the data and the objectives of the study.

Effort is likely to continue in estimating the short- and intermediate-output response of firms to changes in physical, economic and institutional conditions. The exact methodology that will prevail is not clear. There are some who are yet to be convinced that the potential of the representative farm approach has been fully exploited. Regardless of the approach, the ultimate test will be the usefulness of the results. In all probability the reward from these efforts will be in proportion to the effort made in problem identification and specification, the development and refinement of technical coefficients and other relevant data, and the choice of model(s). Attention must be directed toward these things if we hope to duplicate reality—become more predictive—with estimates of how the output from agricultural firms changes in response to changing conditions.

Discussion: The Supply Function in Agriculture Revisited

MARVIN KOTTKE

Sharples took us on a tour of the RFA model, and I want to commend him on the way he conducted the tour. However, after giving us a critical view of the RFA model, he suggested we take the long-run road on our next excursion. As one interested in taking the next excursion, I take issue with his suggestion because I see the long-run supply model as a dead-end road.

In laying the groundwork for my argument, I shall first talk about linkages. In the past decade, as pointed out by Sharples, considerable effort was devoted to finding a linkage between micro and macro supply response by use of the RFA model. The Tweeten-Quance model does not seek a micro-macro linkage but it starts at the opposite pole and attempts to disaggregate the macro in the direction toward micro units. I would submit, however, that the micro-macro linkage is only one of several that need closer attention if we are to make further advances in supply research. Time and spatial linkages are two more that are extremely relevant in contemporary supply behavior. They are especially so because of the current interest in building models for realistic application. In reality, the whole supply problem is intricately interwoven with time, spatial and micro-macro linkages. Our job is to find the best way to slice the problem into manageable relations and still capture the linkage effect.

It is clear that we have been less than successful in finding reasonable micro-macro linkages. But it may be of some comfort to know that we are not alone in the search. A year ago, at our Association's meeting [1], a

---

MARVIN KOTTKE *is professor of agricultural economics at the University of Connecticut.*

session was held on micro-macro linkages in planning a rural economy. The linkage seemed to be elusive in that session also. Even its usefulness was doubted. In contrast, the linkage in supply response would not only be useful, but necessary. In supply analysis, the micro-macro linkage is primarily a feedback effect. We need to capture not only the individual firm's response, but also the feedback to the firms of the effect of their combined responses. It seems to me that a model incorporating cobweb and recursive relations could accomplish this type of micro-macro linkage.

The search for a spatial linkage has been more successful. Spatial linkages can now be handled with quadratic programming models for perfectly competitive industries. We still need to explore ways of introducing imperfectly competitive conditions. In the Northeast dairy adjustment project, we have made a preliminary test of a spatial model incorporating imperfect competition and institutional conditions and the results are promising. In using quadratic programming we have learned that the reasonableness of intercept parameters—their magnitude and their change through time—are just as crucial as elasticities. Hall, *et al.* [2], made the same observation in their application of quadratic programming. As a consequence, I expect that, in the future, we will be putting more effort into testing the reasonableness of the intercept parameters than in estimating elasticities.

Our attempts at handling time linkages in supply response have been rather vague in the past. Usually we have specified a length-of-run for the time dimension. But lengths-of-run, especially intermediate and long-run, are incapable of handling time linkages for the following reasons:

First, in reality, there is no single length-of-run that would represent all firms' supply behavior at a given point or period in calendar time. One of the shortcomings of the RFA model was that all farms were assumed to respond to price in unison during a particular calendar period of time. If one abstracts from calendar time, it is conceptually logical to assume that all firms could respond in unison and make the same length-of-run decision. But, if one dates supply response with calendar time, it is not logical to assume that all firms respond in unison and in the same direction. At any given calendar point in time some farmers may respond positively, others respond inversely, and still others do not respond at all. The differences in each firm's supply behavior are related to structural differences among farms, including such things as rate of technological adoption, capital position, and stage of life.

Second, the theoretical basis of the long-run supply model, particularly in the normative approach, has its roots in the Neo-classical cost curve analysis. Viner's abstract, long-run supply curves which explain increasing, decreasing, or constant cost industries, are quite inept for dealing with supply response in the 1960's. A clue to the long-run supply model's inappropriateness for today's agriculture can be detected in Viner's [3, p. 29] definition of long run, ". . . a sort of 'timeless' long run throughout which nothing new happens except the full mutual adjustment to each other of the primary factors existing at the beginning of the long-run period." This definition clearly rules out technological, institutional and price changes through time. By definition, then, it cannot deal with the major variables in agricultural adjustment, namely, technological change and capital investment.

Third, use of a long-run supply model introduces a semantics problem. Long-run supply has different meanings in different contexts. It means a relatively rigorous static supply curve in the Neo-classical sense. It means a "mongrel" type of supply estimate in the loosely defined sense. It means a time-oriented supply relation in the dynamic sense. To distinguish two of these different meanings, supply researchers use the terms *normative* long-run supply for the RFA type of model, and *positive* long-run supply for the time-series regression type of model. Unfortunately, these two terms have probably generated even more confusion. Nerlove's dynamic long-run supply response differs in meaning from the others in still another way. The incorporation of distributed lags results in a mixture of dynamics and long run—a combination that produces mixed meanings. The proliferation of meanings seems to stem from a desire to stretch the long-run supply model's use beyond its original capacity.

The time has arrived to retire the long-run supply model. In its place I suggest we use comparative statics and dynamic supply models. By use of a comparative statics framework, relations involving technological change, capital investment, institutional change, and stage of life can be brought to bear on the supply estimates through the shift parameters. The comparative static points can be tagged with calendar time without much difficulty and the linkages in time can be accomplished with the dynamic concepts of the cobweb effect, recursive relations and lagged variables.

In conclusion, I agree with Sharples that we need redirection in supply research, but I say we should take a road which offers micro-macro, spatial and time linkages in a semi-dynamic framework.

Discussion: The Supply Function in Agriculture Revisited

W. NEILL SCHALLER

Tweeten and Quance demonstrate imagination in their use of the aggregate production function to measure national supply response for all commodities. While not denying the importance of supply elasticity at such a high level of aggregation, I suspect the authors agree that its usefulness would be enhanced if it could be combined into a larger package of information. I wonder if it would not be possible, now, to develop a consistent, integrated system of commodity supply elasticities at the U.S. level, including cross elasticities—like the demand system developed by Brandow [1].

I should think that the resulting package would contribute more to policy formulation than separate unintegrated studies, and that the system would provide a means of checking for internal consistency.

Elasticities have a long-standing conceptual and numerical meaning to the economist. But it is always difficult to prevent their misinterpretation. Tweeten and Quance recognize the problem. Still, I am not sure that they overcome the likely confusion between economic and calendar time when they define short run as "two years" and long run as "many years."

The Tweeten-Quance paper provides several relevant results, including a courageous offering of point elasticities. They tell us that ". . . there is no basis to conclude that the structure of supply changed between the postwar and prewar periods." They see little basis to conclude that output response to price has increased over time, or that the response differs for rising and falling prices. I had trouble reconciling these remarks with the different elasticities for increasing and decreasing prices, presented at the end of the paper. I suspect that my "hang up" is explained by the word, structure. The authors' results support the hypothesis that the structure of supply was different for increasing and decreasing price years. But what is this "thing" called structure? Is it captured at such a high level of aggregation?

The approach discussed by Sharples is quite different from the one found in the Tweeten-Quance paper. Sharples demonstrates that it is indeed possible to disaggregate total supply, geographically and commodity wise, while maintaining an aggregative point of view. Not many years ago, supply analysts seemed to be clearly either micro-oriented or macro-oriented. The distinction has grown fuzzy. This I regard as a healthy sign.

W. NEILL SCHALLER *is an agricultural economist with the International Agricultural Development Service, USDA.*

Yet, we are still a long way from capitalizing on the complementarity of research techniques and of analyses cast at different levels of aggregation. I agree with Sharples that the micro-macro linkage may have to be informal. In fact, our search for a formal linkage—though scientifically appealing—may explain some lack of progress on achieving the desired complementarity.

It is perhaps significant that neither paper includes a detour into the semantics of normative and predictive research. This, too, is an encouraging sign.

The results presented by Tweeten and Quance obviously apply to output and price levels that have been experienced. Similarly, the estimates discussed by Sharples are determined in part by the range of historical experience. We all know what we are up against when we go beyond that range. But as others have surely said before me, some of our most pressing policy questions require estimates of supply response to conditions not yet experienced. Consider, for example, questions such as (1) How would output respond to substantially lower prices? (2) How much new cropland would come into production if a general cropland retirement program were enacted? (3) What would be the effects on production and income if payment limitations were imposed? These questions are *not* academic. Unfortunately, our tools seem better suited to questions that involve relatively insignificant departures from the current response environment.

The papers presented here tell me that we have made good progress since 1960 when Nerlove and Bachman wrote their important survey article on supply estimation [2]. Useful modifications of existing tools have been developed, and our research has become more mature. But is it possible that the marginal returns to improved use of traditional techniques are now well below the returns that could accrue to research on approaches that lay idle, or do not exist, in our tool kit?

For example, Nerlove and Bachman talked about the need to undertake and extend the use of the producer panel device. What has been done along this line? Could producer panels help answer questions of the kind posed above—those that take us outside of historical experience?

Several years ago, when a relative of mine asked me what my research involved, I explained that I was using mathematical techniques to estimate how farmers would respond to changes in Government programs, prices, and so on. Unimpressed, my relative replied, "If you want to know what farmers would do, why don't you ask them?" The question has nagged me ever since. To my knowledge, we have not really studied the relationship of producer plans to their expectations, nor the relation between their plans and actual behavior. Is the theoretical foundation lacking, or are we somehow tied—intellectually or organizationally—to the kinds of approaches discussed in this session?

AAEA LUNCHEON ADDRESS

CHAIRMAN: W. E. HAMILTON, AMERICAN FARM BUREAU FEDERATION

The Role of the Farm Foundation in Agricultural Economics

JOSEPH ACKERMAN

WHEN I first joined the staff of the Farm Foundation, I spent considerable time attending meetings and conferences. One day one of the individuals that I had seen at many of these conferences said to me, "Every place I go I see you. What is your racket, Joe?" It happened that Henry C. Taylor, who was managing director at that time, was standing next to me, and before I had time to gather my thoughts for a proper reply, he said, "Oh, he has the same function that yeast has in bread." I have often thought of that remark, and after almost thirty years, I can hardly think of a more apt reply. The Farm Foundation is, indeed, much like a leavening agent, for one of its avowed aims is to start action that is self-sustaining and self-multiplying.

The principal founder of the Farm Foundation was Alexander Legge, who was president of the International Harvester Company at the time of his death. At one time he served as chairman of the Farm Board, and this gave him an excellent opportunity to talk with many farmers, businessmen, statesmen, and educators regarding his pet project, a fund that could be used to improve rural life. No agency existed for this specific purpose at the time, and he persuaded others to join with him in sponsoring a foundation.

Frank O. Lowden, another founder, showed his belief in the usefulness of such a foundation by a bequest in his will accompanied by these words: "The quantity and the quality of the rural population is a major and most important factor in determining in the long run the strength, the character, and the well-being of the people of the nation."

The trust agreement which established the Farm Foundation in 1933 provides for the direction of its activities by a Board of Trustees of not fewer than 21 members. For purposes of insuring sound and effective management based upon broad information, seven of these Trustees are to be chosen at large; five are to be experienced in farming; three are to be selected from the executive, teaching, experimental, or extension staffs of the state universities maintaining agricultural departments; and the re-

---

JOSEPH ACKERMAN *is managing director of the Farm Foundation.*

maining six are to represent finance, manufacturing, merchandising, transportation, farm press, and radio as a means of education.

At the first meeting of the organizing committee, Dean Chris Christensen of the University of Wisconsin was asked to obtain the help of E. G. Nourse of the Brookings Institution in investigating various possible fields of activity. In a statement that gave direction to the Board in establishing its philosophy, Dr. Nourse said:

> "If a Foundation is to render a distinctive and positive service, it must settle upon a clearly defined and limited objective of real significance and future value and devise a procedure which will be calculated to stimulate and guide the efforts of other persons or agencies toward the accomplishment of this objective so that their participation may multiply the weight of the foundation's own effort. . . . No social movement can be directed exclusively from the top leaders, however able or disinterested. The movement will 'take' only in proportion as this leadership is effectively interlocked with working relations with the full body of people whom it is designed to benefit."

Dr. Nourse went on to say that the Foundation could and should become a center of leadership and a coordinating agency in helping rural America decide what standards of living it desires and ways of removing obstacles to attainment of those standards.

The key ideas in Dr. Nourse's statement were stimulating the efforts of other agencies to multiply the Foundation's efforts and involving the people in programs designed to benefit them. The Trustees recognized that the limited funds of the Foundation could be used most effectively by supplementing and coordinating the work of other agencies and initiating and demonstrating the value of lines of work that might later be carried on by institutions with greater resources. They also recognized that the process of the farmer thinking through his problems, seeking and finding the solutions, and satisfying the urge for better living was the American free enterprise way of creating a more desirable rural life. Thus, over the years the Farm Foundation has stressed the stimulation of research and experimental work for the study of problems of importance to the rural population, the dissemination of useful information resulting from such study, and the development of understanding and community consciousness.

Dr. Taylor, who served as managing director from 1935 to 1945, was asked to spend his first year investigating the activities of other agencies interested in agriculture and rural welfare and to recommend a program. Following Dr. Taylor's report to the Board, the Board of Trustees decided upon beginning activities in four areas: land tenure, rural education, rural health, and public policies affecting agriculture. Interest in these areas has continued, but the program has been expanded and currently includes work in land economics, public policies affecting agriculture, farm management, water resources, range management, leadership training, rural sociology, agricultural marketing, rural church, and consulting services.

It seemed logical to encourage cooperation among states with similar problems, and much of the work developed more or less naturally by regions: the North Central region, the South, the West, and the Northeast. Most of our activities today are conducted through regional committees, with the state universities in each region represented on these committees. Members of the research committees are appointed by the respective agricultural experiment station directors, and members of the extension committees are appointed by the agricultural extension service directors. The U. S. Department of Agriculture is also represented on each committee. The directors appoint one of their group as administrative advisor to each committee.

In general, the objectives of the research committees are: (1) to identify important problems for study, (2) to develop effective methods for solving them, (3) to generate regional research projects, (4) to provide informal research coordination between two or more states on common problems, and (5) to review and publish manuscripts resulting from the discussions and research of the committee.

The major functions of the extension committees are: (1) to facilitate exchange of new ideas and materials, (2) to explore new methods and procedures in extension education, (3) to prepare basic training and work materials and bulletins for regional use, (4) to promote understanding of subject matter and professional improvement of extension specialists, and (5) to identify emerging problems and assume leadership in new areas of extension emphasis.

Land Economics

One of the first lines of work undertaken was in the field of land tenure for which I served as a specialist. After consulting with the heads of the departments of agricultural economics concerning how we might be most effective, we decided to bring together those interested in this area in order to attack such problems as better land use and conservation, how to attain and maintain the family type farm basic to a satisfactory rural economy, tenancy, getting established in farming, how farmers acquire ownership, and farm land prices.

A land tenure committee was organized in 1939 to undertake cooperative research in the North Central region. Later all of the other states became interested and similar committees were organized in other regions. These groups have served the members and their universities throughout the years as a guiding and coordinating force. Their work, originally confined to land tenure research, has expanded during the years to encompass a broad range of economic problems associated with land and water use. Considerable attention is given to urban problems, which in many instances are inseparable from rural problems.

The land economics committees have set a remarkable record of production of regional and state publications, which have been widely used by research and extension workers not only in this country but in countries all around the world. They have held a number of workshops to identify new problems, to determine the gaps in research, and to explore innovative research methods, thereby significantly advancing the discipline of land economics.

Rural Education

We had a formal project in rural education from 1939 to 1945. This work was under the direction of Iman E. Schatzmann, who worked with a national committee on rural education whose function was to study the conditions of rural education and to recommend ways and means of improving them. The committee, having concluded that the major concern was the quality of teaching and the relating of the work of the schools to the communities in which they were located, initiated four special projects. Three of these were demonstrations in the field of rural elementary education in Illinois, Missouri, and Oklahoma. The fourth was a project in Wisconsin to assist seven selected high schools adjust their curriculums to suit the needs of the rural student body and at the same time to develop the rural high school into a center which could better serve the entire community.

The Committee on Rural Education cooperated with the American Council on Education in holding a conference on "The Rural Child in the War Emergency," which drew national attention to the fact that war conditions threatened to deprive many country children of their educational opportunity. Over 50,000 copies of the conference report were distributed throughout the United States, and considerable radio time was provided free of charge to draw attention to the problem.

The major contribution from the Committee on Rural Education came in its final report, "Still Sits the Schoolhouse by the Road," published in 1943. This 54-page report appraises the existing system of rural education and outlines a program of action for improving it. The committee did excellent work in arousing interest in financing of schools and improvement of curriculums and in-service training. Even though the formal work ended in 1943, interest continued in a rural education project at the University of Chicago for three or four years. Then I also became involved in the public schools as a member of the local board of education, which led to participation in the state school boards association and later the national school boards association. Thus we have had a continued interest in education throughout the years.

Medical Care and Health of Rural People

Another initial project of the Farm Foundation was in medical care and health facilities in rural areas. It was believed that rural people were not receiving adequate medical care The reasons were many, including lack of awareness of the farm people of the full meaning to themselves and their families of modern preventive and curative medicine, inadequate facilities and services, the high cost of rural medical care due to the great distances involved, and failure of the medical profession to recognize the importance of the problem and the opportunities for service.

In 1939 the Farm Foundation initiated a program to help awaken rural people to the importance and possibilities of modern medical care. Financial aid was provided to the University of Nebraska Extension Service for educational work with selected local groups in the more sparsely settled areas. The farm women of Nebraska were particularly interested in this effort. Elin L. Anderson was employed to direct this work. The objective was to get farm people to confer together regarding the best methods for developing more adequate medical care programs for the area. Much attention was given to prepayment plans for medical care as a means of providing preventive as well as curative medical services.

Interest in the project spread beyond Nebraska into the states of Montana, North Dakota, South Dakota, and Wyoming, and a health program was adopted by the Northern Great Plains Advisory Council. From this organized extension effort much interest developed in other states and also among the medical associations.

The Foundation also helped to sponsor annual conferences with representatives of the major farm organizations to promote understanding of ways and means of developing interest, knowledge, and incentive among local groups to help themselves to better health. Many rural health councils were formed and action programs developed.

In 1949 a research grant was given to Michigan State College for a two-year study which resulted in a comprehensive book, *Community Health Action,* outlining how many communities had succeeded in organizing to meet their rural health needs.

The Farm Foundation continues its interest in this area through participation in the Advisory Committee of the American Medical Association's Council on Rural Health.

Public Policies Affecting Agriculture

Much time was devoted to the study of public policies affecting agriculture with the assistance of Howard J. Stover, who was employed as a statistician by the Farm Foundation in 1937. Material was published on "Immediate Backgrounds of Present Agricultural Policies and Programs" and "The Farmer in the Groupistic Regime."

Dr. Taylor helped organize the National Farm Institute at Des Moines, Iowa, as a forum for discussion of agricultural problems and also helped develop the Institute's first programs on land tenure, the farmer's stake in foreign trade, and the common interests of agriculture, labor, and industry.

He was also interested in the development of a project on world trade in agricultural products, which was supported by funds from the Rockefeller Foundation and sponsored by the International Institute of Agriculture at Rome. This work resulted in the publication in 1940 by the International Institute of Agriculture of *World Trade in Agricultural Products,* a volume of over 1,100 pages. In 1943, Dr. Taylor and his wife, Ann D. Taylor, with the assistance of the U.S. Department of Agriculture, published a summary of the volume under the same title.

Frank W. Peck, Managing Director of the Foundation from 1945 to 1954, had an extension and farm credit background. Under his direction, new emphasis was given to extension activities. In 1950, the Foundation held a national conference on agricultural policy primarily for extension directors to point out extension opportunities in this area of concern. It was felt that extension could render an important service in helping farm people develop an enlightened understanding of the economic, social, and political consequences of alternative policies, thus enabling them to participate more effectively in policy decisions.

The following year a series of regional conferences were sponsored by a national policy committee which was organized following the first conference. This national committee consisted of one extension representative, one research economist, and one extension director from each of the four extension regions. This committee has planned and conducted eighteen annual training conferences for extension economists actively engaged in public policy work. Each of these conferences has been designed to improve understanding of the major emerging agricultural policy issues. The proceedings each year have been published by the Farm Foundation in a series of reports under the title, "Increasing Understanding of Public Problems and Policies." This past year, because of the many demands we have had for these proceedings, R. J. Hildreth, Associate Director of the Farm Foundation, prepared a book of forty readings, selected from these proceedings because of their current usefulness.

The Foundation also brought together a group of eminent agricultural economists to prepare a consensus statement with respect to federal price support programs. This group presented its conclusions in a widely read booklet, *Turning the Searchlight on Farm Policy.* The group reviewed the evolution of agricultural price support legislation, influenced as it has been by war and peace, by technological progress, and inflationary disturbances. It tried to distill the lessons taught both by the experience and by the study as a basis for consideration of future plans and programs. Even though this booklet was published in 1952, there is still a tremendous demand for it.

In 1963 the Farm Foundation received a grant of $60,000 from the Ford Foundation to be used over a period of five years in support of liberal education programs for public affairs specialists and administrators in the agricultural extension services. Plans for this project were developed by the National Agricultural Policy Committee in cooperation with the Center for Agricultural and Economic Development of Iowa State University, the Agricultural Policy Institute of North Carolina State University, and the Federal Extension Service. The four regional committees established under this program have been tremendously productive during the short period of their existence. They have prepared numerous publications for use by extension workers in their respective regions. They have prepared a set of slides and an accompanying script to be used in conjunction with a manual, "Your Part in Agricultural Policy." They cooperated with the national committee in the development of a series of extension leaflets on "People and Income in Rural America." These leaflets explore both the commercial farm problem and the low-income problem in rural America.

A number of important activities were undertaken through a coordinating committee consisting of representatives of the National Agricultural Policy Committee, the Center for Agricultural and Economic Development of Iowa State University, the Agricultural Policy Institute of North Carolina State University, the Federal Extension Service, and the Farm Foundation. This group prepared a series of leaflets on "The Farm Problem—What Are the Choices?" It also prepared a series of leaflets on "World Trade: What Are the Issues?" as well as a third series of leaflets on "Developing Human Resources for Economic Growth." In 1968, this group held a seminar to explore the relevance of university research and education, particularly in the social sciences, to existing and emergent social problems.

Each year financial assistance is provided to 100 county agents from the various states to attend three-week training courses in agricultural policy, which are offered at Colorado State University and the University of Arizona. These scholarships have been provided since 1953.

Farm Management

The North Central Farm Management Research and Extension Committees were organized in 1946 and were soon followed by the establishment of similar committees in the South, the Northeast, and the West. Currently all 50 states are represented on the four regional farm management research committees and all states except Alaska are represented on the four regional farm management extension committees.

The research committees have been active over the years in the development of research projects, many of which became established as independent technical projects. One of the more productive technical projects in the North Central region was a regional study of decision-making processes. The findings were published by Iowa State University Press in a book, *A Study of Managerial Processes of Midwestern Farms.* A Southern technical study of farming adjustment opportunities, terminated in 1968, resulted in a regional publication, "Cotton: Effects of Allotments on Supply and Farm Resource Use." Many state publications also have resulted from this project.

More important perhaps than the regional projects have been the cooperative efforts in holding workshops and seminars on methodological approaches to farm management problems. The early discussions by the committees, both formal and informal, had a significant bearing on both the direction of methodology and the progress in farm management research. The current discussions of the implications of structural changes in agriculture for farm management research will undoubtedly point up areas requiring research in the years ahead.

Many publications have also resulted from the cooperative efforts of the extension committees. Yet I feel that probably the most significant contribution of the committees in recent years has been their exploration of the question of farm management in the years ahead. A regional workshop held in the North Central states was attended by most of the farm management extension personnel in the region, Federal Extension Service representatives, and many visitors. The objective of this workshop was to contribute to professional improvement of participants through appraisal of the economic climate and the educational needs of changing clientele groups and examination of new approaches in filling these needs.

In looking ahead, we can see that sound decision making, which is basic to good farm management, will require the consideration of an increasing number of factors. It will call for the application of the principles of economics to specific problems, a knowledge of the many economic forces affecting the farm business, and an evaluation of new technologies. The farm management committees are trying to develop programs to meet these needs.

Water Resources and Range Management

Closely related to land economics and farm management are the committees on water resources and range management of the Western Agricultural Economics Research Council, which are supported from a grant made by the Foundation to the Council.

The reports of conferences sponsored by the Water Resources Committee continue to serve as an important source of reference material. The committee prepared a book dealing with economics and public policy in water resource development comprised of chapters written by leading economists in the field. The demand for the book indicates that it has met a need for authoritative material on the subject.

The Range Use and Development Committee initiated a project, W-79, Economic Analysis of Range and Ranch Management Decisions on Western Livestock Ranches. As a part of this project, several states have prepared basic budget data for more than two hundred specific ranching situations. Recently much attention has been given to economic analysis of the demand for outdoor recreation.

Leadership Training

The Foundation initially was interested in improving the work of the departments of agricultural economics and provided funds to the University of Chicago from 1938 to 1942 for scholarships for agricultural economists. Mr. Peck renewed the program of providing scholarships for a year's training, but the emphasis was changed and the scholarships were made available to extension workers, particularly those responsible for extension supervision and administration. The theory behind this change in emphasis was that the training provided would benefit not only the extension workers but also extension's large clientele, the farm people. These scholarships have been provided since 1947. In addition, the Foundation has since 1950 provided 20 scholarships to supervisors each year to attend the extension summer school course for extension supervisors.

Between 1946 and 1953 funds were provided for four workshops for extension administrators, two workshops for home demonstration leaders, and an extension visual aids workshop. All of these workshops were designed to increase understanding of the roles and responsibilities of extension workers and to improve the effectiveness of extension programs.

Two series of workshops which the Foundation helped sponsor played a very important role in the improvement of agricultural instruction. The first was a series of workshops for the Southern states on improvement of college teaching in agriculture. The discussions centered on concepts and principles of teaching, evaluating the effectiveness of teaching, means of improving teaching, and improving the teacher as a person. The funds for this series of five conferences came primarily from the Danforth Foundation.

The second series of workshops, for deans and directors of resident instruction in agriculture, were held on a national basis. Five workshops have been held, and currently a second series of five workshops are being held with a grant to the Farm Foundation from the Sears-Roebuck Foundation. The purpose of these workshops is to bring together those who have major administrative responsibility in resident instruction for discussion of problems associated with both curriculum and personnel. These workshops have resulted in many adjustments in college curriculums with a view to providing more adequate training for a highly technical commercial agriculture.

Rural Sociology

In 1947 the directors of agricultural experiment stations approached the Farm Foundation concerning support for a committee in rural sociology. As a result of the initial meeting with the directors, the Foundation sponsored in 1949 a comprehensive study of the research and extension activities of the land-grant universities and colleges in rural sociology. The report of this study, conducted under the leadership of F. D. Farrell, President Emeritus of Kansas State College, was published in 1950 under the title, "Human Relations in Agriculture and Farm Life." The report was presented to the Rural Sociological Society at its annual meeting in 1950, and the Society recommended that the Foundation sponsor a conference or workshop to study the main issues defined in the report. The Society felt that some of the causes of frustration among rural sociologists and the problems involved in the training of rural sociology personnel required special attention.

This interest, along with urging from the directors of agricultural experiment stations, led the Foundation to organize a committee of research and extension representatives in the North Central region in 1951. Without going into detail, let us just say that this committee has had a greater impact on the research and extension activities in its field throughout the region and throughout the United States than any other one committee that we support. The committee has made tremendous strides in important areas, including the diffusion and acceptance of new ideas among farmers, the social process, resident and extension teaching in rural sociology, career choices of rural youth in a changing society, the role of leadership in the social system, and many more.

We now have a rural sociology committee in each of the four regions. All of these committees are concerned with the stimulation and improvement of work in rural sociology and the contributions which improved knowledge of human relations can make to other disciplines and to agriculture.

Agricultural Marketing

The Farm Foundation sponsors four extension marketing committees and has actively participated in the work of the Western Research and

North Central Research Committees. The four regional extension marketing committees define problems and develop and conduct educational programs on a regional and coordinated state basis to assist farmers, managers of marketing firms, and consumers with marketing decisions. They have also devoted major efforts to training to improve the competency of marketing specialists and the field staffs in the respective regions. The research committees have made significant contributions toward understanding of market structure and marketing efficiency.

The marketing system has grown in size and also influence. It is demanding higher and more uniform quality and is setting other specifications for farm products. It is exerting a strong influence on the structure of agriculture. Consequently, the marketing committees will have to continue to study the impact of marketing upon agriculture and to identify and evaluate alternative methods of accomplishing market objectives. Currently the committees are giving considerable attention to the question of bargaining as a part of the marketing process.

Rural Church

Another project that has perhaps received less recognition than the others is the Farm Foundation's work with church groups. One of the early ideas of the Foundation was that rural pastors could minister more effectively to the spiritual life through better understanding of the economic realities of rural life and ways of working more successfully with people. Grants-in-aid were made from 1939 to 1944 to three institutions for teaching agricultural economics and rural sociology to rural pastors in summer short courses. These institutions were the Garrett Biblical Institute, the National Catholic Rural Life Conference, and the Pacific School of Religion. Over the years this program has expanded until it includes ten institutions.

The Foundation has also given financial aid to the Committee on Continuing Education for Town and Country Pastors at the Land-Grant Universities. This committee prepared a brochure outlining areas of needed church oriented research and suggested areas of instruction at land-grant universities for developing better economic understanding among those responsible for religious activities in smaller communities. The committee also sponsored a series of regional two-week schools for pastors to develop understanding of economic trends and social processes and the role of the church in the community.

History of Agricultural Economics

Following retirement from his position as managing director of the Farm Foundation, Dr. Taylor and his wife, Ann D. Taylor, wrote a book, *The Story of Agricultural Economics in the United States, 1840–1932,* under the sponsorship of the Farm Foundation. This comprehensive historical treatment of the men, services, and ideas that contributed to the growth of agricultural economics was published in 1952 and still is widely used as a reference.

Conclusion

One of the important roles of the Farm Foundation has been that of coordinator. The regional committees of land-grant university and U.S. Department of Agriculture personnel which we sponsor have proved a most effective approach to coordination. They have provided a means of pooling experience and thinking in studying problems which extend beyond state borders. They have helped avoid duplication of effort and have saved time and money for the research and extension agencies. Coordination has led to integration of activities of limited scope into larger more meaningful undertakings. It has provided a broader view of problems, facilitated long-time planning, and given more effective direction to the work. In short, it has led to better results from the limited funds available.

Another role that the Farm Foundation has filled is that of innovator. Through our committees and through workshops we have tried to provide an environment conducive to creative thinking. The discussions have stimulated imaginative new ideas for conducting both research and extension activities. Such discussions led to the application of linear programming methods to farm management problems. Through the efforts of the farm management extension committees, projects have been developed for electronic processing of farm records to provide farmers more promptly with data for farm business analysis. The land economics committees have enlisted the aid of lawyers in studying the legal aspects of land economics problems. These are but a few examples of new approaches devised by the committees.

A third role of the Farm Foundation has been that of educator. It has provided funds for training conferences and training courses and for publishing and distributing the results of conferences and studies. The purpose of this education has been professional improvement of researchers and educators as well as broadening of the concepts and understanding of the people. The end objective has been the development of sound economic thinking to enable people to act responsibly and wisely in making their own decisions.

Still another role of the Foundation has been that of "lookout." The Farm Foundation and its committees continue to scan the horizon for emerging problems. The committees continually reorganize and redirect their programs to fill the continuing need for knowledge to keep ahead of our dynamic agriculture. The first major reorganization in the over-all regional work in agricultural economics has recently taken place in the West, where the committees on farm management, marketing, water resources, and range use have been restructured into three committees on commercial agriculture, natural resource development, and community and human resources development. The Western Agricultural Economics Research Council felt that this restructuring would lead to more meaningful research through consideration of problems in a broader and more realistic context.

If we have in a small way succeeded in helping to direct attention to problems of the over-all economy as well as to solving day-to-day problems of the farmer and his family, if our work has helped provide farmers with information to aid them in acting intelligently and effectively in private matters concerning the efficiency of their operations and in public matters affecting their welfare, then our work has been most worth while.

THE POTENTIAL ROLE OF CONTROL THEORY IN POLICY FORMULATION FOR THE U.S. AGRICULTURAL INDUSTRY

CHAIRMAN: KARL A. FOX, IOWA STATE UNIVERSITY

What Does Control Theory Have to Offer?*

GERHARD TINTNER

WE INTRODUCE a few definitions. We have a system, in our examples simple linear difference or differential equations connecting certain inputs and outputs. There is a control variable which should enable us to produce some desired output. The output is the controlled variable. Open loop control exists where the output has no effect upon the input. Feedback provides the means of feeding back the output in order to enable a comparison with the desired output. Closed loop control means a system where output has effect on the input in order to obtain the desired result. Adaptive systems take change in the environment into account, especially stochastic variations.

1. Deterministic models

One of the most interesting developments in modern economics is the utilization of ideas which have proven their usefulness in electrical and communications engineering [1, 21, 22, 16]. In a sense, these ideas correspond to the economic concept of a multiplier [1].

We shall illustrate control theory with the help of a very simple problem in agricultural production in India. Using Indian data for 1951–52 to 1963–64 [20] and denoting by A_t real per capita agricultural production and by E_t real per capita government expenditure on agriculture in India, we derive empirically the following relation:

$$A_t = 0.0463 + \underset{(0.14723)}{0.87325\, A_{t-1}} + \underset{(1.7068)}{1.21524\, E_{t-4}} \tag{1}$$

The multiple correlation coefficient is 0.94012, its square $R^2 = 0.883$ shows, that about 88% of the total variance of Indian per capita agricultural real

---

GERHARD TINTNER *is distinguished professor of economics and mathematics at the University of Southern California.*

production is explained by the relation. The figures in brackets below the regression coefficients denote standard errors.

This equation is easily integrated and gives the general relation for A_t using the observed values of A_{12} and $E_t (t \leq 12)$

$$
\begin{aligned}
(2) \qquad A_t = {} & 0.36529 + 1.09681(0.87325)^{t-3} + 1.70681 \\
& + [(0.0211)(0.87325)^{t-4} + 0.0278(0.87325)^{t-5} \\
& + 0.0338(0.87325)^{t-6} + 0.0516(0.87325)^{t-7} \\
& + 0.0619(0.87325)^{t-8} + 0.0360(0.87325)^{t-9} \\
& + 0.0379(0.87325)^{t-10} + 0.0405(0.87325)^{t-11} \\
& + 0.0417(0.97325)^{t-12} + 0.0437(0.87325)^{t-13} \\
& + 0.0452(0.87325)^{t-14} + 0.0529(0.87325)^{t-15} \\
& + 0.0548(0.87325)^{t-16} + E_{13}(0.87325)^{t-17} \\
& + E_{14}(0.87325)^{t-18} + \cdots + E_{t-4}] \qquad (t \geq 17)
\end{aligned}
$$

Imposing the condition that $A_t \geq A_{16} = 0.8854$ (agricultural production for 1967/68) we derive:

$$
(3) \qquad A_t \geq 0.0542
$$

The sum:

$$
\begin{aligned}
(4) \qquad S = {} & A_{17} + A_{18} + A_{19} + A_{20} + A_{21} = 3.5901 + 4.7189E_{13} \\
& + 4.012E_{14} + 3.2031E_{15} + 2.2764E_{16} + 1.21524E_{17}
\end{aligned}
$$

This is the sum of agricultural production 1968/69 to 1972/73. We want to maximize it under the condition that $A_t \geq A_{16} = 0.8854$ for $t = 17$, 18, 19, 20, 21. This is to say, agricultural production should in no year be smaller than in 1967/68. This implies that $E_t \geq 0.0542$ for $t = 13$, 14, 15, 16, 17. The E_t, government expenditure on Indian agriculture, real per capita, are our control variables. If the total expenditure available $E = E_{13} + E_{14} + E_{15} + E_{16} + E_{17} > 5(0.0542) = 0.2710$, then the best allocation is as follows: Allocate $E_{13} = E - 0.2710$, $E_{14} = E_{15} = E_{16} = E_{17} = 0.0542$.

A very important idea in deterministic control theory is the maximum principle of Pontryagin [6]. A special version of Pontryagin's maximum principle [11, 6] is due to Rozonoer [11]. Assume we have a number of n variables $x_i(t)$ $(0 \leq t \leq T)$ and we want to maximize

$$
F = \sum_{i=1}^{n} c_i x_i(T)
$$

i.e., a linear function of the terminal state of the system. The system is described by the differential equations:

$$
(5) \qquad \dot{x}_i(t) = f_i(x_1, x_2, \cdots, x_n, u_1, u_2, \cdots, u_m) \qquad i = 1, 2, \cdots, n
$$

where dots denote time derivatives, $x(0) = x_0$ and the u_j are controls, which are constrained to lie in a closed set U.

We form the Hamiltonian:

$$H = \sum_{i=1}^{n} p_i f_i \tag{6}$$

The conditions:

$$\dot{x}_i = \partial H / \partial p_i \tag{7}$$

give us the above system of differential equations (5). From:

$$\dot{p}_i = -\partial H / \partial x_i \tag{8}$$

and $p_i(T) = c_i$ we determine the $p_i(t)$. The condition:

$$M = \max_{u_k} H \tag{9}$$

gives the optimal controls [3].

If we use the integral of our difference equation derived empirically from Indian data for food production in India we have:

$$dA(t)/dt = A(t) = 0.0463 - 0.135A(t) + 1.21524E(t-4) \tag{10}$$

We want to maximize $A(20)$, i.e., agricultural production in 1971/72.

We form the Hamiltonian:

$$H = p(t)[0.0463 - 0.135A(t) + 1.21524E(t-4)] \tag{11}$$

From

$$A(t) = \partial H / \partial p \tag{12}$$

we get again the above differential equation for $A(t)$, (10).

$$\dot{p}(t) = -\partial H / \partial A = 0.135p(t) \tag{13}$$

and the condition: $p(20) = 1$ gives:

$$p(t) = 0.067e^{0.135t} \tag{14}$$

We see from the Hamiltonian, that for a maximum $E(t-4) = \text{sign } p(t)$. If we have the condition that $0 \leq E(t) \leq E$, where E is a constant (the maximum expenditure for agriculture available) then we must make $E(t) = E$.

Using the last observation $A(12) = 0.9401$ and finding the integral of (10), we derive from $A(20)$:

$$A(20) = 0.360 + 9.002E \tag{15}$$

Hence, if $E = 0.05$, like in recent years $A(20) = 0.810$, indicating a strong decline of real per capita agricultural production in India if government expenditure is not increased. However, if we make $E = 0.1$, roughly a doubling of recent government expenditure on agriculture in India, we obtain: $A(20) = 1.260$, an increase of 34% over the last observed agricultural production.

A discrete version of the maximum principle is given by Rozonoer [12]. See also [4]. Consider n first order difference equations in the variables $x_{1t}, x_{2t} \cdots x_{nt}$

$$x_{it+1} - x_{it} = \Delta x_{it} = f_i(x_{1t}, x_{2t} \cdots x_{nt}, u_{1t}, u_{2t} \cdots u_{mt}, t) \quad i = 1, 2, \cdots, n \tag{16}$$

Here the u_{jt} are control variables and must lie in a closed set U. The object is the maximization of

$$S = \sum_{i=1}^{n} c_i x_{iT} \tag{17}$$

where x_{iT} is the terminal value.

We introduce n function of time p_{it} and form the Hamiltonian:

$$H = \sum_{i=1}^{n} p_{it} f_i \tag{18}$$

We have:

$$\Delta x_{it} = \partial H / \partial p_{it} \tag{19}$$

which gives us the above system of difference equations (16).

$$\Delta p_{it-1} = - \partial H / \partial x_{it} \tag{20}$$

and the boundary conditions:

$$x_{i0} = a_i \tag{21}$$

$$p_{it-1} = c_i \tag{22}$$

Then the maximum principle says: Find the maximum:

$$M = \underset{u_j}{\text{Max}}\, H \tag{23}$$

which will determine the optimal controls.

Consider now the previous model of agricultural production in India. We derive the relation:

$$A_{t+1} - A_t = \Delta A_t = 0.0463 - 0.12695 A_t + 1.21424 E_{t-3} \tag{24}$$

Now we form the Hamiltonian function:

$$H = p_t(0.0463 - 0.12685 A_t + 1.21524 E_{t-4}) \tag{25}$$

If we want to maximize A_{20} i.e., agricultural production for 1971/72 we have:

(26) $$\Delta A_t = \partial H/\partial p_t$$

which is the above difference equation for A_t (24). Also:

(27) $$\Delta p_{t-1} = -\partial H/\partial A_t = 0.12685 p_t$$

with the initial condition:

(28) $$p(20) = 1$$

This gives $p_t = 0.066\ (1.145)^t$. We see from the Hamiltonian that the maximum is given by $E(t\text{-}4) = \text{sign}\ p_t$. If again $0 \leq E_t \leq E$ we must make $E_t = E$ in order to attain the optimum.

Using formula (2) we obtain for $A(20)$:

(29) $$A(20) = 0.768 + 5.633E$$

For $E=0.05$, $A(20)=1.05$, i.e., agricultural production similar to the present value. If $E=0.1$ $A(20)=1.33$ i.e., if real per capita government agriculture is approximately doubled, there will be an increase of about 41% in real per capita agricultural output in India in 1971/72.

The following is based upon [3]. See also: [15, 19]. Consider first a continuous deterministic control problem. Given an initial time t_0 and a terminal time T, also that

(30) $$x(t_0) = x_0$$

We want x to get to the origin $x=0$ and the cost is:

(31) $$C = \int_0^T u^2(t)dt + x^2(T)$$

where the first term denotes the cost of control, the second the deviation from the origin. The motion of x is given by:

(32) $$dx/dt = ax(t) + bu(t)$$

Introduce a Lagrange multiplier $L(t)$. We have:

(33) $$dL/dt = -aL$$

(34) $$L(T) = 2x(T)$$

Optimal control is given by:

(35) $$2u + Lb = 0$$

Hence we have:

(36) $$L(t) = 2x(T)e^{a(T-t)}$$

$$u(t) = -x(T)be^{a(T-t)} \tag{37}$$

Control varies exponentially with time.

The ultimate results are:

$$x(T) = \frac{e^{a(T-t)}x(t)}{1 - (b^2/2a) + (b^2/2a)e^{2a(T-t)}} \tag{38}$$

$$u(t) = \frac{be^{2a(T-t)}x(t)}{1 - (b^2/2a) + (b^2/2a)e^{2a(T-t)}} \tag{39}$$

This is the feedback solution. The same result might be obtained by dynamic programming [2, 4, 9].

Applying these methods to our example of agricultural production in India, we minimize:

$$F = \int_0^T u^2(t)dt - A(T)^2 \tag{40}$$

This is the same as maximizing the terminal value $A(T)$ and minimizing the cost $u(t)$: $u(t) = E(t-4)$.

The conditions are:

$$A(t) = 0.0463 - 0.135A(t) + 1.21524u(t) \tag{41}$$

We introduce a Lagrange multiplier $L(t)$ and form the expression:

$$G = u^2(t) + L(t)[A(t) - 0.0463 - 0.135A(t) - 1.21524u(t)] \tag{42}$$

The boundary conditions are:

$$A(12) = 0.9401 \tag{43}$$

$$L(T) = 2A(T) \tag{44}$$

we find the necessary conditions for a minimum:

$$\partial G/\partial u = 2u(t) - 1.21524L(t) = 0 \tag{45}$$

$$d(\partial G/\partial A)/dt = (\partial G/\partial A) \tag{46}$$

$$\dot{L}(t) = 0.135L(t) \tag{47}$$

The results are:

$$L(t) = 2A(T)e^{-0.135T+0.135t} \tag{48}$$

$$u(t) = 1.21524e^{-0.135T+0.135t} \tag{49}$$

$$\begin{aligned} A(t) &= 0.342 + [3.050 - 117.214A(T)e^{-0.135T}]e^{-0.135t} \\ &\quad + 4.501A(T)e^{-0.135T+0.135t} \end{aligned} \tag{50}$$

$$A(t-4) = 0.342 + 5.234e - {}^{0.135t} - 201.139A(T)e^{-0.135T}e^{-0.135t} + 2.624A(T)e^{-0.135T+0.135t} \tag{51}$$

$$A(t) = \frac{A(t-4) - 0.342 - 5.234e^{-0.135t}}{2.624e^{-0.135T+0.135t} - 201.139e^{-0.135T-0.135t}} \tag{52}$$

Finally, since:

$$u(t+4) = E(t) = 2.085e^{-0.135T+0.135t} \tag{53}$$

we have for the control variable:

$$E(t) = \frac{2.085A(t) - 0.713e^{-0.135t} - 10.913}{2.624 - 201.139e^{-0.135t}} \tag{54}$$

Assume that for $t = 15$ we have $A(t) = 1$. Then the optimal $E(t)$ from formula (53) is $E(15) = 0.588$, but this is about ten times the current government expenditure on agriculture. This feedback relation gives the control variable $E(t)$ (real per capita government expenditure on agriculture in India) as a function of the contemporary state variable $A(t)$ (real per capita agricultural production in India).

2. Stochastic models

A possible generalization of deterministic control theory consists in the assumption that all parameters involved are random variables with a known joint probability distribution. The methods used in the following models are neither very realistic nor efficient. But they point to the need of taking the random influences in economics into account as much as policy decisions are concerned [22].

Consider now a continuous stochastic problem [3]. Let x be determined by:

$$x(t+\Delta t) = x(t) + [ax(t) + bu(t)]\Delta t + \xi(t)(\Delta t) \tag{55}$$

where $\xi(t)$ is stochastic process with:

$$E\xi(\Delta t) = 0 \tag{56}$$

$$E\xi^2(\Delta t) = \sigma^2\Delta t \tag{57}$$

$$E\xi^n(\Delta t) = 0(\Delta t) \qquad n > 2 \tag{58}$$

$\xi(\Delta t_1), \cdots \xi(\Delta t_n)$ are independent in not overlapping intervals $\Delta t_1, \cdots \Delta t_n$. E is mathematical expectation. If $z(t)$ is a Brownian motion process

$$\xi(\Delta t) = \Delta z_t = z(t+\Delta t) - z(t) \tag{59}$$

We wish to minimize:

$$E\int_{t_0}^{T} u^2(t)dt + x^2(T) = \int_{t_0}^{T} u^2dt + [Ex(T)]^2 \tag{60}$$

One solution of this problem might be obtained by the certainty equivalent. We replace the stochastic process $\xi(\Delta t)$ by its mean value, zero [17, 18, 14, 13]. Let $f(x, t)$ be the minimum value of the objective function:

$$f(x, t) = \min_u E_\xi[u^2\Delta t + f\{x + (ax + bu)\Delta t + \epsilon, t + \Delta t\}] \tag{61}$$

$$0 = \min_u [u^2 + (\partial f/\partial x)(ax + bu) + 1/2\sigma^2(\partial^2 f/\partial x^2) + (\partial f/\partial t)] \tag{62}$$

$$u = -b(\partial f/\partial x)/2 \tag{63}$$

The result is the same as in the deterministic case [36, 38].

Now we assume that the variance of $\xi(t)$ depends upon the control decision, with no randomness in the evolution of x if no control is exerted.

$$E[\xi(\Delta t)]^2 = u^2\sigma^2\Delta t \tag{64}$$

where σ is a constant. The criterion function is simply

$$E[x(T)^2] \tag{65}$$

$$x(t + \Delta t) = x(t) + [bu(t)]\Delta t + \xi(t)\Delta t \tag{66}$$

Open loop control implies that the variance of $x(T)$ is:

$$\int_{t_0}^{T} u^2(t)\sigma^2 dt \tag{67}$$

and the criterion function is:

$$[Ex(T)]^2 + \int_{t_0}^{T} u^2\sigma^2 dt \tag{68}$$

Now the Lagrange multiplier is a constant, $L = 2Ex(T)$.

Optimal control is given by:

$$u(t) = E[x(T)]b/\sigma^2 \tag{69}$$

We find empirically in our example for Indian agricultural production: $b = 1.21524$ and $\sigma^2 = 0.049246$. Hence the optimal control if we minimize $\int_{t_0}^{T} u^2(t)dt - [Ex(T)]^2$ is given by:

$$E(t - 4) = EA(T)(24.677) \tag{70}$$

This is the same as:

$$u(t) = \frac{x(t)}{b[T - t + (\sigma^2/b^2)]} \tag{71}$$

In our example this is:

$$E(t-4) = u(t) = \frac{A(t)}{1.21524(T-t) + 0.033349} \tag{72}$$

$$E(t) = \frac{A(t-4)}{1.21524(T-t-4) + 0.033349} \tag{73}$$

The expected terminal value of x is given by

$$Ex(T) = \frac{\sigma^2 x(t_0)}{b^2[T - t_0 + (\sigma^2/b^2)]} \tag{74}$$

In our example

$$EA(T) = \frac{0.033349A(t_0)}{T - t_0 + 0.033349} \tag{75}$$

The variance of the random variable $x(T)$ is:

$$\sigma^2_{x(T)} = \frac{\sigma^2 x^2(t_0)(T - t_0)}{b^2[T - t + (\sigma^2/b^2)]^2} \tag{76}$$

This is in our example:

$$\sigma^2_{A(T)} = \frac{0.033349A^2(t_0)(T - t_0)}{(T - t + 0.03349)^2} \tag{77}$$

The value of the criterion function is:

$$E[x(T)]^2 = \frac{\sigma^2 x^2(t_0)}{b^2[T - t_0 + (\sigma^2/b^2)]} \tag{78}$$

This is in our example:

$$E[A(T)]^2 = \frac{0.033349A(t_0)^2}{T - t + 0.03349} \tag{79}$$

Open loop optimal feedback proceeds as follows: The equation of motion is:

$$x(t + \Delta t) = x(t) - \frac{x(t)\Delta t}{T - t + (\sigma^2/b^2)} + \xi(\Delta t) \tag{80}$$

Let $f(x, t) = E[x(T)]$
Dynamic programming [2, 9] gives:

$$f(x, t) = E_\xi\left\{ f\left[x - \frac{x\Delta t}{T - t + (\sigma^2/b^2)} + \xi, t + \Delta t \right] \right\} \tag{81}$$

Letting $\Delta t \to 0$

$$(82)\qquad 0 = x(\partial f/\partial x)/[T - t + (\sigma^2/b^2)] + x^2\sigma^2(\partial^2 f/\partial x^2)/2b^2[(T - t + (\sigma^2/b^2)]^2 + (\partial f/\partial t)$$

Hence:

$$(83)\qquad f(x, t) = x^2 \exp\{1 - \sigma^2/b^2[(T - t + (\sigma^2/b^2)] + 2\log(\sigma^2/b^2) - 2\log[T - t + (\sigma^2/b^2)]\}$$

$$(84)\qquad E[x^2(T)] = \sigma^2 x(t_0)/b^2[T - t_0 + (\sigma^2/b^2)]$$

This is again the same result as for the pure open loop process (78).

For feedback we use the optimality principle of dynamic programming. Let now $f(x, t)$ be the value of the criterion if we start with x at time t: $t_0 < t < T$.

$$(85)\qquad f(x, t) = \min_u E_\xi[f(x + bu\Delta t + \xi, t + \Delta t)]$$

$$(86)\qquad 0 = \min_u [bu(\partial f/\partial x) + 1/2u^2\sigma^2(\partial^2 f/\partial x^2) + (\partial f/\partial t)]$$

This yields after some transformations:

$$(87)\qquad f(x, t) = [\exp - (b^2/\sigma^2)(T - t)]x^2$$

$$(88)\qquad u = bx/\sigma^2$$

In our example:

$$(89)\qquad f(A, t) = \exp - 0.033349(T - t)A^2(t)$$

$$(90)\qquad u(t) = 24.677A(t)$$

This is evidently a very unrealistic solution.
Let now $h(x, t)$ be the expected terminal value of x using this control. Dynamic programming gives:

$$(91)\qquad h(x, t) = E_\xi h[x - (b^2x/\sigma^2)\Delta t + \xi, t + \Delta t]$$

with the boundary condition:

$$(92)\qquad h(x, T) = x$$

The solution is:

$$(93)\qquad h(x, t) = e^{-(b^2/\sigma^2)(T-t)}x$$

This gives for our example, dealing with agricultural production in India:

$$(94)\qquad h(A, t) = e^{-.033349(T-t)}A(t)$$

Control Theory for Agricultural Policy: Methods and Problems in Operational Models*

OSCAR R. BURT

IN VIEW of the large amount of research by agricultural economists that leans heavily for justification on its contribution to policy decisions, it is surprising that so little effort has been devoted to systematic utilization of such research. Or considered from the other side, we might have expected more research devoted explicitly to utilization of objective information for policy purposes, and that work could exert its influence on the research that purports to be policy oriented. We have apparently conceived policy decisions as being of such a subjective nature that researchers should stop short of anything like an optimization model for policy purposes. An exception to this point of view is that expressed in the recent book by Fox, Sengupta, and Thorbecke [5].

Recently, there has been an inclination to move further in the direction of trying to quantify social costs asssociated with various policy actions [11, 12, 16, 17], but we need to go another step by using these quantitative measures in the objective function of an intertemporal optimization model. Gustafson's pioneering work in models for optimal grain storage is an example of the direction that we should be moving [7], as is also the general theory of economic policy set out in [5].

Such models take us into the realm of modern control theory. Control theory encompasses not only recent extensions of the calculus of variations, including Pontryagin's work [13], but also discrete time optimization models such as Rosen's convex programming formulations [14] and Bellman's dynamic programming [3]. The latter encompasses the methodology used by Gustafson in his storage control models. Although the classical continuous time models are most applicable to physical phenomena, the discrete time models are usually better adapted to economics. Most decision problems in economics are periodic, and in agriculture, the period is often a year. Of course, economic problems can be approximated by continuous variational models, but numerical solution of these models usually requires discrete approximation methods. Therefore, it would seem advantageous to use a discrete model at the start since it is more realistic and can be solved directly. One advantage of a continuous model is the ability to treat end points of the time horizon analytically through the transversality conditions. For numerical analysis, the discrete model is satisfactory on this point, too, because the time horizon can be arbitrarily extended until the solution values

---

* Journal paper No. 951 of the Montana Agricultural Experiment Station.

OSCAR R. BURT *is professor of agricultural economics and economics at Montana State University.*

of the control and state variables in the terminal period indicate that any addition to the time horizon would be redundant.

The discussion of this paper is in the context of discrete time, but for those accustomed to continuous time control theory, the conceptual basis is essentially the same. We assume a multi-stage decision process, where a stage is defined by an interval of time, say, a year. The criterion function is taken as the sum of discounted returns (costs) over all stages; the specific definition of returns (costs) is delayed until later. The following variables and relationships are basic elements of the model:

s_t is a vector of state variables that describes the decision process at any given stage t;

x_t is a vector of decision variables that is subject to control at each stage t;

$s_{t+1}=s_t+f(x_t, s_t)$ is a difference equation that expresses the state vector in stage $t+1$ as a function of the state and decision vectors in stage t;

$G(x_t, s_t)$ is the return (cost) function that associates a value with each combination of state and decision at each stage;

β is a discount factor constrained by $0<\beta<1$.

We will be considering control problems of the form

$$\max_{x_t} \sum_{t=0}^{T} G(x_t, s_t)\beta^t \tag{1}$$

subject to

$$s_{t+1} = s_t + f(x_t, s_t),\ s_0 = K;\ x_t \epsilon R(s_t),$$

where $R(s_t)$ is a region to which the control vector is constrained. For simplicity, the function $G(x_t, s_t)$ has not been made explicitly a function of time.

Temporal decision models are necessary for agricultural policy because of lagged supply responses and opportunities for storage of many commodities. Lags in consumer adjustments may also be of some importance, but are likely to play a minor role compared to storage and lags in supply. Storage is of particular importance for crops that are subject to large variations in production beyond the control of farmers, such as dry-land wheat production in the Great Plains. State variables of policy decision models will usually be functions of lagged prices and/or quantities of commodities in storage. Models that involve livestock will probably contain inventories of livestock groups, such as beef cows, as state variables. Control variables can take several forms such as prices, quantities, and acres planted.

Space does not permit coverage of stochastic models in the discussion below, but the most critical part of the model where random elements enter is in the difference equation. In many formulations, $f(x_t, s_t)$ is a random variable which requires a Markovian sequential decision model [10]. Often $G(x_t, s_t)$ is a random variable, but this is easily handled by an expected value criterion.

An illustrative example may clarify the relevance of (1) as an aid to agricultural policy decisions. Administered prices for fluid milk are institutionalized in the United States to such an extent that we seldom question the practice. Control theory in conjunction with reliable estimates of demand and supply equations can provide an objective basis for pricing. We specify a set of plausible assumptions for the structure of demand and supply equations in a hypothetical dairy region operated under administered prices. For simplicity, we take actual price instead of minimum price paid to farmers as the control variable and begin with a criterion of net returns to farmers, although a social value criterion is discussed later. Use of minimum prices, as is found in most marketing orders, would merely change the lower bound on price (the control variable) since a minimum price below some level would be ineffective and market equilibrium price would prevail. We abstract from seasonal pricing difficulties and it is convenient to think of the decision period as a year.

We assume a distributed lag supply equation

$$q_t^s = b_0 + b_1 P^f{}_{t-1} + b_2 p^m{}_{t-1} + b_3 q^s{}_{t-1}, \tag{2}$$

and separate demand equations for fluid and manufacturing utilization

$$\begin{aligned} q_t^f &= a_0 - a_1 p_t^f \\ p_t^m &= c, \end{aligned} \tag{4}$$

where the superscripts f, m, and s denote fluid milk, manufacturing milk, and total milk supplied, respectively. The constant price demand equation for the manufacturing market implies that the region is a small part of the total market. Total utilization of supply implies the identity, $q_t^s = q_t^f + q_t^m$, and the above are farm level price relationships.

The supply equation with lagged explanatory variables is the source of a nontrivial intertemporal decision problem. Otherwise, in the absence of storage, pricing decisions would be static and each period could be optimized independently. The control variable is p_t^f, price in the fluid market. State variables are p_{t-1}^f and q_{t-1}^s which stem from the supply equation (2). Lagged price of manufacturing milk, p_{t-1}^m, is not required as a state variable as a result of the simplified demand equation (4).

To avoid confusion in writing the difference equations, let the state variables be

$$s_t^1 = p_{t-1}^f \quad \text{and} \quad s_t^2 = q_{t-1}^s, \tag{5}$$

and the decision variable be $x_t^1 = p_t^f$. The two difference equations are

$$(6)\qquad s_{t+1}^1 = x_t^1 \quad \text{and} \quad s_{t+1}^2 = b_o + b_1 s_t^1 + b_2 c + b_3 s_t^2.$$

In defining the criterion function of net returns to farmers, a cost of production must be deducted from gross returns. Let that cost be $C(q_t^s)$, which is assumed to reflect private opportunity costs of all factors used in milk production. Then the net return at year t is

$$\begin{aligned}(7)\quad & p_t^f q_t^f + c(q_t^s - q_t^f) - C(q_t^s) \\ &= x_t^1(a_o - a_1 x_t^1) + c[b_o + b_1 s_t^1 + b_2 c + b_3 s_t^2 - (a_o - a_1 x_t^1)] \\ &\quad - C(b_o + b_1 s_t^1 + b_2 c + b_3 s_t^2) = G(x_t, s_t).\end{aligned}$$

That completes all the necessary relations to put fluid milk pricing in the control model (1), at least within the context of this illustrative example using discounted private net returns to producers as the objective function.

Criterion Functions

Probably the most challenging aspect of using control theory for policy decisions is choosing an appropriate and meaningful criterion function. Obviously, net returns to farmers, such as that employed in the above example, is unsatisfactory since value to consumers is completely ignored. Net market values might be useful if additional constraints were imposed on the model which gave some consideration to consumer interests, For example, prices might be limited to an arbitrary rate of increase, or quantity produced could be kept above some lower limit. In the case of very inelastic demand, a lower limit on quantity would appear promising.

Nevertheless, a more fruitful approach would seem to be in the direction of using social value measures directly in the criterion function and imposing ancillary constraints to protect farmers' income position, but measurement of social value is a nebulous task, to say the least. In spite of the criticisms that have been waged against it, net area above the supply curve and under the demand curve, and its generalization by Hotelling [9] to a line integral for multiple commodities, looks the most promising as a social value measure. The above described area assumes an orientation with price the dependent and quantity the independent variable. From an operational point of view, the critical question is whether marginal utility of money can be taken as approximately constant on the region of variation in prices and quantities in an empirical analysis.

Looking at the demand side first, we have a technical requirement on the system of demand equations that must be met before a line integral can yield an unambiguous measure. Meeting this technical condition, which is the restricted integrability conditions, does not guarantee that marginal utility of money can be taken as constant. The problem can be analyzed with the aid of Slutsky's equation expressed in elasticities [6, p. 180],

$$\alpha_i e_{ik} - \alpha_k e_{ki} = \alpha_i \alpha_k (E_i - E_k), \tag{8}$$

where α_j and E_j are the budget proportion and income elasticity, respectively, for commodity j, and e_{ik} is the price elasticity of commodity i with respect to price k.

It follows directly from (8) that if the income elasticities are equal for commodities i and k,

$$\alpha_i e_{ik} = \alpha_k e_{ki}, \tag{9}$$

and (9) implies

$$\frac{\partial q_i}{\partial p_k} = \frac{\partial q_k}{\partial p_i} \tag{10}$$

which is the restricted integrability condition on the pair of demand functions. For obvious reasons, relation (10) will be referred to as the symmetry condition. Equality of income elasticities is a very restrictive assumption, but it can be relaxed by noting that if the budget proportions are small and the difference in income elasticities is in the same order of magnitude as (or smaller than) the cross price elasticities, than (9) and (10) hold approximately. This latter proposition will be recognized as a generalization of a theorem presented by Wold [19, p. 112]. The crux of the proposition is that direct substitution effects dominate the differential income effects for the pair of commodities.

If a set of agricultural commodities is closely interrelated in demand, we would expect the income elasticities to be similar (with some exceptions, of course), and equation (10) would be approximately met if the budget proportions were small. On the other hand, those commodities that are not closely related can probably be treated independently without too much error. The obvious difficulty of dealing with anything approaching an inferior good stems from the budget proportion being large. The limited statistical analysis that has focused on the symmetry condition does not refute it [15, p. 642; 4, p. 14].

We can probably justify the symmetry condition for a system of demand equations as an approximation. However, we have not avoided the issue of the constancy of the marginal utility of money merely by the symmetry condition. If symmetry is plausible primarily from equal income elasticities, we have only permitted treatment of the group of commodities essentially as a single commodity. Small budget proportions and relatively small variations on prices and quantities in the region of measurement are the only basis for assuming marginal utility of money approximately constant.

If for no other reason than practical necessity, empirical estimation of social value will probably be attempted by using the demand curve of the "representative consumer" (per capita demand equation) and associated values weighted by population to get total value. Variation in personal income is a source of possibly large differences in marginal utility of money among consumers but the estimated per capita demand equation will contain income as a concomitant variable. Therefore, per capita social value can be computed from the demand equation with median income, or some other measure of central tendency, substituted into the equation and that value multiplied by population to get total value. An alternative that is more consistent with market valuation (but which I feel is inferior as a social value measure) is to stratify the population with respect to income, compute a per capita social value for each stratum, and form a weighted sum of these values using population in each stratum as weights.

Theoretical treatment of supply has been rather limited, but Hotelling's early work showed the symmetry condition is met for supply equations generated by optimizing firms without money capital limitations [8]. These results suggest that the symmetry condition is probably met approximately in an agricultural industry dominated by commercial farms, as opposed to subsistence farming.

Another problem of measurement arises in regard to distributed lag demand and supply equations. Use of area under demand and above supply equations as a measure of social value is predicated on the assumption that these are the classical, static relations of abstract theory. Therefore, distributed lag equations should be unscrambled from their empirical basis as much as possible and transformed into a long-run static concept.

As an example, take the simple fitted equation

$$y_t = a + bp_{t-1} + cy_{t-1}$$

which has as its theoretical basis

$$(12) \qquad y_t = a' + b[p_{t-1} + \lambda p_{t-2} + \lambda^2 p_{t-3} + \cdots], \qquad |\lambda| < 1,$$

and the coefficients of (11) and (12) are related by $a = a'(1-\lambda)$, $c = \lambda$. One might be tempted to use (11) directly to get a measure of value, and treat y_{t-1} as a state variable that enters in a dynamic way by shifting the curve, but the value measure would be derived from a conditioned short-run function and not the long-run curve of static theory. Therefore, we must go to (12) which has its difficulties arising from an infinite series of lagged prices. How can an integral of value be deduced from such an equation?

Equation (12) can be written with a single price by defining a weighted average price, using the linear coefficients as weights,

$$(13) \qquad z_{t-1} = \sum_{j=1}^{\infty} b\lambda^{j-1} p_{t-j} \Big/ \sum_{j=1}^{\infty} b\lambda^{j-1},$$

and taking the sum of the coefficients as the linear coefficient on the new price variable. Thus, we have

$$y_t = a' + b' z_{t-1}$$

where

$$b' = \sum_{j=1}^{\infty} b\lambda^{j-1}. \tag{14}$$

The coefficient b' will be recognized as that used in distributed lag analysis to derive long-run elasticities. The correct measure of social value (cost) is an integral associated with equation (14).

Using properties of geometric progressions, (13) reduces to

$$z_{t-1} = (1 - \lambda) \sum_{j=1}^{\infty} \lambda^{j-1} p_{t-j} \tag{15}$$

and $b' = b/(1-\lambda)$. Relation (15) is the source of a *single* state variable to "carry along" all the information needed about previous prices, and the first order difference equation

$$z_t = (1 - \lambda) p_t + \lambda z_{t-1} \tag{16}$$

is the recurrence relation needed in model (1).

In general, a weighted average of lagged prices can be used as a single price in linear distributed lag equations, and the reduced equation in this single price variable is the source of an appropriate social value (cost) measure. However, more than one state variable will be necessary to specify the state of the decision process unless the lags are assumed to follow a convenient pattern, such as geometrically dampened effects that produced (16). Imposition of the symmetry constraint on a system of lagged equations will require the constraint to fall on the "long-run" relations; thus, in linear relations, certain pairs of sums of linear coefficients will be forced to have equal members.

Going back to the dairy pricing example and using a net social value criterion instead of market net returns, we need to transform the lagged supply equation into its long-run counterpart. Iterating (2) in the variable q_t^s and assuming $|b_3| < 1$,

$$\begin{aligned} q_t^s = b_0/(1 - b_3) &+ b_1(p_{t-1}^f + b_3 p_{t-2}^f + b_3^2 p_{t-3}^f + \cdots) \\ &+ b_2(p_{t-1}^m + b_3 p_{t-2}^m + b_3^2 p_{t-3}^m + \cdots), \end{aligned}$$

which is the supply equation expressed with a distributed lag coefficient on price that diminishes geometrically by the factor b_3. The long-run equation in weighted prices is

$$q_t^s = b_0' + b_1' z_{t-1}^f + b_2' z_{t-1}^m, \tag{17}$$

where $\quad b_j' = b_j/(1 - b_3), \qquad j = 0, 1, 2,$

and

$$z_{t-1}{}^{k} = (1 - b_3) \sum_{i=1}^{\infty} b_3{}^{i-1} p_{t-1}{}^{k}, \qquad k = f, m. \tag{18}$$

However, the manufacturing milk demand expressed by (4) lets us simplify (17) to

$$q_t{}^{s} = b_0'' + b_1' z_{t-1}{}^{f}, \tag{19}$$

where $b_0'' = b_0' + b_2'c$.

We again use $x_t{}^1 = p_t{}^f$ as the control variable, but now there is only one state variable, $s_t{}^1 = z_{t-1}{}^f$, and the state variable difference equation is

$$s_{t+1}{}^1 = (1 - b_3) x_t{}^1 + b_3 s_t{}^1. \tag{20}$$

The control variable, $p_t{}^f$, does not affect social costs in period t, but instead affects cost in period $t+1$ and all subsequent periods. However, the influence of $p_t{}^f$ in period $t+1$ and later is taken into account by the state variable.

Let us write the inverse of (3), with price as the dependent variable, as

$$p_t{}^f = D(q_t{}^s), \tag{21}$$

and the inverse of (19) is defined

$$s_t{}^1 = S(q_t{}^f). \tag{22}$$

Quantity supplied in period t is given by (19) which is abbreviated $\phi(s_t{}^1)$; likewise, let (3) be $\psi(x_t{}^1)$. The control variable, $x_t{}^1 = p_t{}^f$, is restricted to values greater than or equal to the price that would equate total quantity supplied with that demanded in the fluid market. Price in the fluid market cannot drop below this level because price would not ration the limited supply, but as long as price exceeds this level, excess supply (for the fluid market) is sold in the manufacturing market. This minimal price is given by solution of

$$\psi(x_t{}^1) = \phi(s_t{}^1) \tag{23}$$

in the variable $x_t{}^1$ which makes the minimal price a function of the state variable, $s_t{}^1$.

If the supply equation, $S(q)$, intersects the quantity axis at a positive quantity, that point is denoted q_o. For that situation, the criterion function is

$$G(x_t, s_t) = \int_0^{q_o} D(q)dq + \int_{q_o}^{\psi(x_t^1)} [D(q) - S(q)]dq + \int_{\psi(x_t 1)}^{\psi(s_t 1)} [c - S(q)]dq; \tag{24}$$

otherwise the first two integrals condense to the second with the lower limit changed to zero. Should the demand function for manufacturing milk be more complicated than (4), an additional state variable is required, but the criterion function is essentially the same. It is important to realize that the absolute level of the criterion function in (24) has no meaning; but it is a useful means to evaluate pricing policies that involve variations in prices and quantities within the region of experienced price-quantity relations. Implementation of policies that move prices and quantities outside this region should be gradual so that the information on demand and supply relationships generated by the changes can be fed back, through estimation, into the model.

Adaptive Models and Numerical Solution

Comprehensive decision models for policy will require systems of demand and supply equations for several commodities. The burden of statistical estimation may appear formidable, but the state of the arts in econometrics is ready for it. The greatest obstacle is one of organizing and soliciting the talent required for a sufficiently long period of time.

An operational model for policy purposes must be modified each year as additional information unfolds which means that a team of econometricians must be continually checking, testing, and reformulating the model. Some automated adaptive features can be implemented, such as in engineering adaptive control processes [2] or automatic statistical updating [1], but an economic decision model of this nature will probably require a good deal of subjective adaptation. The model should be formulated to permit maximum adjustment, and should incorporate all sources of information that look promising and are quantifiable.

There will be an interaction between the control model itself and the estimated relationships used within the model over time. To illustrate this point, let us look at supply estimation when the control model uses acreage allotments as a control variable in contrast to setting prices paid to farmers without allotments. The acreage allotments make statistical estimation of supply as a meaningful measure of social cost more difficult because net effects of price are confounded with the influence of allotments. Such relationships between choice of control variables and ability to estimate required empirical measures should be given serious consideration in developing control models for agriculture, assuming, of course, that the models might be used.

There are several alternatives for getting solutions to the optimization problem of (1), and experience thus far does not provide a good basis for choice among them. A direct approach is to use nonlinear programming to solve (1), which is the method proposed by Rosen [14]. A difficulty here is that computer capacity is easily exhausted if the number of state and control variables is large and a long time horizon is used. One way to cope with computer capacity is to divide the time horizon into several segments; then solve the short time horizon problem associated with the *last* segment for many initial state vectors s_o, and fit a suitable function to the optimized criterion function with s_o as a vector of independent variables. Let the fitted relation be $h_o(s_o)$. Then $h_o(s_o)$ is used as the *terminal* value of a second problem associated with the next to the last segment of the planning horizon which is solved by nonlinear programming for many initial state vectors s_0, and the fitted relation to that set of solutions is $h_1(s_o)$. The iterative process is repeated until a solution is achieved for the first segment of the planning horizon. Actually, the above described procedure is an application of dynamic programming to a sequence of nonlinear programming problems that have been parameterized in the state vector. The method looks promising for linear demand and supply equations coupled with linear difference equations since this specification would make (1) a quadratic program. Parametric methods in quadratic programming are relatively simple and the algorithms quite efficient.

Another approach is Wilson's [18], using the method of conjugate gradients. It also is especially appealing for quadratic criterion functions since convergence is known to be rapid in that case. Wilson's method contains a decomposition principle that partitions the problem in the time dimension which is advantageous for limited computer capacity.

Dynamic programming can be applied directly to the problem; the functional equation associated with (1) is

$$v_n(s) = \operatorname*{Max}_{x}\,[G(x, s) + \beta v_{n-1}(s + f(x, s))], \qquad x \in R(s). \tag{25}$$

Numerical solution of the functional equation in (25) has its difficulties when s is a vector of more than two or three components. Bellman has suggested possible means of overcoming this difficulty, but analysts have not experimented in this direction very much [2, p. 244]. One advantage of dynamic programming is that stochastic features can be incorporated with less difficulty than under alternative methods.

Discussion: The Potential Role of Control Theory

RUSSELL G. THOMPSON

IN ECONOMICS, control theory is rapidly becoming one of the fundamental tools of analysis. This development would be expected, of course, since this theory represents a dynamic method of constrained optimization.

In particular, control theory is ideally suited to the study of programming problems over time; and, in this context, economists are deriving computable Fisherian formulas [1] for the firm's investment, inventory, and money demands (*cf.* [4]).

Here today, both Tintner and Burt have presented some macro applications of these methods. The AAEA audience will surely find them interesting. Their approach represents a fitting introduction. In fact, it is so fitting that I decided to deviate from normal procedures, and present a micro example to further illuminate the potential of these methods.

This example will be a stochastic production-inventory model for irrigated farming where the water source is an irreplenishible underground aquifer. It will be developed as a discrete-time optimal control problem using a method by Thompson *et al.* [5].

RUSSELL G. THOMPSON *is professor of economics and statistics, Texas A&M University.*

Initially, some definitions and assumptions will be introduced; and a production-inventory model where the rainfall is regarded as known—Problem I—will be specified. The rainfall will next be regarded as not being known precisely, but having a known probability distribution. *It will further be visualized that plans must be made regardless of this randomness; and the farmer must optimally determine the amount of rainfall to plan for.* Another control variable is introduced; and penalties for under- and over-anticipated rainfall are assigned. The added variable is included as a constraint; and the expected values of the penalties are included in the objective function. This transformed problem—Problem II—is deterministic in form, and may be analyzed by received methods.

The Formulation

Definitions[1]

w_t is water pumped; v_t is the rainfall planned for. These are the unknown controls, $t=1, 2, \cdots, T$.

x_t is water in the underground aquifer; y_t is soil moisture in inventory. These are the unknown states, $t=1, 2, \cdots, T$.

α_t is per unit net returns excluding pumping costs; f_t is production; g_t is pumping costs; γ_t and ζ_t are increases in soil moisture due to rainfall and irrigation, respectively; ξ_t is the decrease in soil moisture resulting from transpiration, evaporation, and percolation; τ_0 is pumping capacity; δ_t is the discount rate; and $\phi_t = 1/(1+\delta_t)^t$ is the discount function. These functions are regarded as known, $t=1, 2, \cdots, T$.

r_t is rainfall. It is regarded as known in Problem I, and as a random variable having a known probability distribution, $F_t(r_t)$, in Problem II, $t=1, 2, \cdots, T$.

Assumptions

f_t and $-g_t$ are strictly concave in their respective arguments; r_t is nonnegative; and $F_t(r_t)$ is aboslutely continuous with density $f_t(r_t) \neq 0$, $t=1, 2, \cdots, T$.

$\alpha_t, \gamma_t, \xi_t, \delta_t, \zeta_t$, and τ_o are positive; $f_t, g_t, \partial f_t/\partial y_t$, and $-\partial g_t/\partial x_t$ are positive for all feasible values of their respective arguments with $f_t(0)=0$ and $g_t(0^+)=+\infty$, $t=1, 2, \cdots, T$.

Problem I, where r_t is regarded as known

Maximize

$$I = \sum_{t=1}^{T} \phi_t\{\alpha_t f_t(\xi_t y_t) - g_t(x_t)\}$$

---

[1] The subscript "*t*" means in period *t*.

subject to the difference equations

(I.1) $x_t - x_{t-1} = -w_t$, x_0 given and positive,

(I.2) $y_t - y_{t-1} = \gamma_t r_t + \zeta_t w_t - \xi_t y_t$, y_0 given and positive, and subject to the inequalities

(I.3) $0 \leq w_t \leq \tau_0$, where $t = 1, 2, \cdots, T$.

As mentioned above, we will next visualize r_t as not being known exactly, but having a known probability distribution, $F_t(r_t)$. Moreover, plans must be made regardless of this randomness. Let $v_t = (y_t - y_{t-1} - \zeta_t w_t + \xi_t y_t)/\gamma_t$; and let $(r_t - v_t)^+ = r_t - v_t$ if $r_t - v_t \geq 0$ and zero othrewise, $(r_t - v_t)^- = v_t - r_t$ if $v_t - r_t > 0$ and zero otherwise. Also let $m_t(r_t - v_t)^+$ be the penalty for under-anticipated rainfall, and $m_t(r_t - v_t)^-$ be the penalty for over-anticipated rainfall. Then let

$$H_t(v_t) = E[m_t(r_t - v_t)^+ + m_t(r_t - v_t)^-],$$

or

$$H_t(v_t) = \int_{vt}^{\infty} m_t(r_t - v_t)^+ dF_t(r_t) + \int_0^{v_t} m_t(r_t - v_t)^- dF_t(r_t).$$

$H_t(v_t)$ will be regarded as convex in v_t. (Sufficient mathematical requirements for the convexity of H_t in v_t are straightforward, but will not be made here in the interest of brevity.) To further simplify, difference equation (I.1) will be solved for x_t; and the solution will be substituted into g_t.

Problem II, where r_t is visualized as random[2]

Maximize

$$I = \sum_{t=0}^{T} \phi_t \left\{ \alpha_t f_t(\xi_t y_t) - g_t\left(x_0 - \sum_{i=1}^{t} w_i\right) - H_t(v_t) \right\}$$

subject to the difference equations

(II.1) $y_t - y_{t-1} = \gamma_t v_t + \zeta_t w_t - \xi_t y_t$, y_0 known and positive, and subject to the inequalities

(II. 2) $0 \leq w_t \leq \tau_0$, (II.3) $0 \leq v_t$, where $t = 1, 2, \cdots, T$.

Problem II is a deterministic convex programming problem, linear in all the constraints. Thus, the requirements for Theorems 1, 2, and 3 by Kuhn and Tucker [3] are satisfied.

---

[2] Note that Problem II may be extended to allow for the following possibilities: (1) a soil nutrient inventory, fertilizer supplementation, and interaction between soil nutrient and moisture use, (2) investments in farming and irrigation capacity, (3) cash flows, money costs, and money earnings, (4) income and property taxes, (5) standard input-output relations, and (6) stochastic prices [2].

The Lagrangian function for Problem II and associated preliminary results

$$L(v_t, w_t, y_t, p_t, \mu_t, \lambda_t, \theta_t, t = 1, 2, \cdots, T)$$

$$= \sum_{t=1}^{T} \phi_t \left\{ \alpha_t f_t(\xi_t y_t) - g_t\left(x_0 - \sum_{i=1}^{t} w_i \right) - H_t(v_t) \right\}$$

$$+ \sum_{t=1}^{T} p_t(y_{t-1} - y_t + \gamma_t v_t + \zeta_t w_t - \xi_t y_t)$$

$$- \sum_{t=1}^{T} \mu_t(w_t - \tau_0) + \sum_{t=1}^{T} \lambda_t w_t + \sum_{t=1}^{T} \theta_t v_t.$$

Let v_t^0, w_t^0, y_t^0, denote the optimal controls and states, $t = 1, 2, \cdots, T$. Then multipliers p_t^0, $\mu_t^0 \geq 0$, $\lambda_t^0 \geq 0$, $\theta_t^0 \geq 0$, $t = 1, 2, \cdots, T$, exist such that $\partial L^0/\partial v_t = 0$, $\partial L^0/\partial w_t = 0$, $\partial L^0/\partial y_t = 0$, $\mu_t^0(w_t^0 - \tau^0) = 0$, $\lambda_t^0 w_t^0 = 0$, $\theta_t^0 w_t^0 = 0$, $t = 1, 2, \cdots, T$, hold at the optimum (with (II.1), (II.2), and (II.3) also being satisfied).

Let $A_t(v_t) = p_t^0 \gamma_t - \phi_t \partial H_t(v)/\partial v_t$; and

$$B_t(w_t) = \phi_t \partial g_t\left(x_0 - \sum_{i=1}^{t-1} w_i^0 - w_t \right) / \partial w_t + p_t^0 \zeta_t.$$

It is easily shown[3] that A_t is strictly decreasing in v_t, B_t is strictly decreasing in w_t, and $A_t(v_t) = 0$ for some feasible v_t (when Problem II has a solution).

The Basic Decision-Making Rules

Theorem

(a) $B_t(0) < 0$ and $A_t(0) \leq 0$ implies $w_t^0 = 0 = v_t^0$; (b) $B_t(\tau_0) > 0$ and $A_t(0) \leq 0$ implies $w_t^0 = \tau_0$ and $v_t^0 = 0$; (c) $B_t(0) < 0$, $A_t(0) > 0$ but $A_t(v_t^*) = 0$ for some feasible v_t^* implies $w_t^0 = 0$ and $v_t^0 = v_t^*$; (d) $B_t(\tau^0) > 0$, $A_t(0) > 0$ but $A_t(v_t^*) = 0$ for some feasible v_t^* implies $w_t^0 = \tau_0$ and $v_t^0 = v_t^*$; (e) $B_t(0) \geq 0$, $B_t(\tau_0) \leq 0$, and $A_t(0) \leq 0$ implies $v_t^0 = 0$ and w_t^0 is the unique solution to $B_t(w_t) = 0$; and (f) $B_t(0) \geq 0$, $B_t(\tau_0) \leq 0$, $A_t(0) > 0$ but $A_t(v_t^*) = 0$ for some feasible v_t^* implies w_t^0 is the unique solution to $B_t(w_t) = 0$ and $v_t^0 = v_t^*$. These results hold for $t = 1, 2, \cdots, T$. (See Thompson *et al.* [5] for proof, and note solutions can be computed by convex programming algorithms.)

Discussion: The Potential Role of Control Theory

FREDERICK V. WAUGH

To some Congressmen, and to some businessmen, "controls" is a dirty word. To them, controls are elaborate and detailed regulations of all industries by a bunch of impractical, longhaired bureaucrats who never won an election or met a payroll.

I take it that this is not what my good friend, Gerhard Tintner, means by "control variables." Nor what the officers of the Association meant by arranging a session on "control theory." Any nation's economy is subject to all sorts of controls. Some are Government regulations. Some are policies and practices of industry. Some are institutional arrangements, habits, and customs. Some are the controls of a free market.

Few, if any, economists would advocate controls for the sake of controls. But some kinds and degrees of controls are essential—whether by Government or not. No one really wants anarchy. The goals of society can best be determined by the people, preferably through an elected Congress. The technically qualified economist can be most helpful by indicating what policies are needed to reach whatever goals are set by the people.

Both Tintner and Burt have presented useful theoretical models. Such models can help us understand basic principles. But I am sure Tintner and Burt would agree that pure mathematics alone will not give us good economic policies. First, we need adequate, reliable statistics to make our models realistic. Second, the economist, the mathematician, and the statistician must work with competent men in other disciplines: the physical scientist, the sociologist, the historian, the political scientist, and others.

Some of us like to dream about the possibility of automatic controls in economics. Such controls would be like the thermostat in my house. When the temperature falls below 70 degrees, the thermostat sends a message to the heater; the gas is turned off and the cycle repeats itself all day with-

---

FREDERICK V. WAUGH, *formerly with USDA, now holds appointments with the U.S. Department of the Interior and the University of Maryland.*

out any human attention. Perhaps some day we can operate our tax system in a similar manner. Instead of debating for two years whether to change our tax rate, perhaps we can decide to change it automatically when certain economic indexes reach predetermined levels. We already have a few such automatic controls. For example, wage rates are commonly adjusted automatically to reflect changes in the Consumer's Price Index. Perhaps in time other automatic controls will be found to be practicable, useful, and generally acceptable.

But I suspect it will be a long time before we are ready to rely upon any automatic mechanism to control our whole economy. I do not think the economist alone can ever define "net social value," nor do I believe that the "competitive equilibrium" would always be ideal, even if we knew how to accomplish it. For the next few centuries, at least, I think econometricians can contribute most by helping to work out a very few controls in limited areas. Both Tintner and Burt discuss agricultural controls. We have had some experience with such controls. Not all of this experience has been completely satisfactory. The econometrician should be able to improve this situation. He could help develop a better formula for "parity prices," or a more intelligent program of reserve stocks. He could help to relieve the desperate situation in India by finding out how to increase agricultural output. For such purposes, he needs not only a theoretical model; he needs reliable statistics, competently analyzed and interpreted.

This, in my opinion, is the weakness of 95 percent of the so-called "econometric" literature: it *should* combine theory, mathematics, and statistical analysis. But too often it is only some fancy mathematics, with trivial attention (if any) to the practical problems of statistical analysis. The best book I know of on econometrics is the one by Tintner [1]. It covers a variety of techniques and shows how to apply them to practical statistical problems. We need more applied research on economic controls.

TECHNOLOGY, DEMOGRAPHY, AND U.S. RURAL ECONOMIC POLICY

CHAIRMAN: VERNON W. RUTTAN, UNIVERSITY OF MINNESOTA

Demographic and Social Considerations for U.S. Rural Economic Policy

CALVIN L. BEALE

IF A demographer has anything worth saying, he welcomes the chance to expose others to the approach of his field and the implications of his insights. But this joy is tempered when he is asked to do so in years ending in 8, or even 7 or 6. For, although his wisdom may abound in the early years of a decade, much of it has become commonplace or clouded with uncertainty near the end of the decennial period. This is particularly true when the subject considered is the rural population, for, as officially defined, it can be measured only in a full census and cannot be acceptably approximated in intercensal sample surveys. However, if an opportunity for such a presentation does not come in a year ending in 2 or 3 or 4, one does the best one can in a year ending in 8.

There are some facets of the rural demographic picture that it is unnecessary to demonstrate. Everyone knows that with the decline in farm employment the farm population has dropped rapidly. We have all heard that the rural population is a smaller proportion of the total population than formerly. And, for that matter, it is now reasonably common knowledge that the majority of rural people no longer live on farms or work directly in farming. Each of these facts has clearly affected the thinking of policy makers, in the last decade particularly. There are other demographic conditions, however, that are not as clear cut or as well understood either in their trends or their implications. I should like to focus on several such features that I regard as significant and in need of explication.

One recurring problem in furnishing information about rural areas is the inevitable and understandable desire of policy makers to have generalizations and brevity. Yet, in the case of rural areas, national generalizations can often be misleading and potentially harmful. If there is one point about American rural demography that needs emphasis, it is that there are widely divergent demographic conditions in the rural population associated with different geographic regions and ethno-cultural

---

CALVIN L. BEALE *is leader of the population studies group, Economic Development Division, Economic Research Service, USDA.*

groups. This is true of population growth trends, migration patterns, fertility, age structure, and changes in small towns.

Fertility

The discussion can begin with fertility, for the typically higher rural than urban fertility has always been a factor underlying the age structure of the rural population and fostering outmigration. In 1960 the cumulative fertility of women nearing the end of the childbearing period (35–44 years) was about 28 percent higher in rural areas than in urban.[1] The potential for population increase was at least 250 percent greater per generation among rural women than urban, however, for only that proportion of childbearing above generational replacement needs goes to increase the population. Rural women averaged about 950 to 1,000 children per 1,000 women above replacement needs, whereas urban women averaged only 250 to 300 per 1,000 above the replacement requirement.[2] Thus, although urban women 35 to 44 years numbered more than 70 percent of all U.S. women of that age, they contributed little more than 40 percent of the childbearing involved in growth of the national population.

More important to our discussion is the fact that there is more variation in fertility among rural people than urban. Particularly, there are many more areas and population groups of high fertility among rural people. Figure 1 illustrates the distribution of high fertility populations in the United States. Four or more children ever born per ever married woman aged 35 to 44 years (in 1960) is the index of high fertility used. Under current mortality rates, populations of this fertility double themselves—or more—in a generation, a period of about 25 to 27 years. It is immediately noticeable from the map that metropolitan counties are conspicuously absent (there are only two, of Mexican-American population), nor is there any meaningful representation from the entire Northeast, the Lower Great Lakes Region, the Corn Belt, the southern Wheat Belt, and the Pacific States. These areas simply do not have abnormally high growth potential from either their rural or urban populations.

In almost all cases the high fertility level is associated with a comparatively distinctive ethnic or subcultural population. With the exception of metropolitan areas, most of the entire span of the Southern Coastal Plain is represented for the Negro population, from Southern Maryland to East Texas. The high average Negro fertility in this region is the product of the rural population; southern urban Negro women average only 3 children

---

[1] In the United States as a whole, the number of children ever born per 1,000 women ever married, 35–44 years old, was 3,127 for rural women and 2,436 for urban women [8, p. 1–212].

[2] Assuming a requirement for generational population replacement of about 2,150–2,200 children ever born per 1,000 women ever married, 35–44 years old.

Figure 1.

per woman. Although 4 or more children per woman has been used as the measure of high fertility, the Negro rural population averaged better than 4.5 children per woman. Furthermore, Negro rural fertility increased during the 1950's. In only one of the counties of high Negro fertility did the white women average 4 or more children.

In the Southwest are sizeable areas in which the Mexican-American population has high average fertility and accounts for a significant fraction of the entire population. The average level of rural Mexican-American childbearing is nearly 5 children per woman.

Other areas on the map are those in which the white population—other than Mexican-American in the Southwest—averages 4 or more children per woman. There are no large concentrations of such areas. The most populous is the Coal Fields Area in the heart of the Southern Appalachians. Similar in character to one another but not always contiguous, are small predominantly Mormon areas of Utah and Idaho, and a scattering of counties in the Northern Plains that are usually of German Catholic population.

In addition, there are areas in which American Indians or Alaskan natives comprise 10 or more percent of the population and have high fertility. Alaska and the Four Corners area of the Southwest are the most important concentrations. The average is fully 5 children per woman.

This map, then, identifies the groups, together with their locations, whose fertility is exceptionally high by modern standards, leading to high continued potential growth. They are preponderantly rural and, with the exception of the Mormon and German Catholic groups, are characterized by widespread poverty, low educational attainment, and high social visibility. With the same exceptions, they are the very groups whose urban migration gives most concern to cities—indeed, they may be the only groups whose migration troubles urban interests—and they comprised the four rural elements who were represented in the Poor Peoples Campaign to Washington in 1968. Judging from the limited attitudinal data available, many of the families in these groups are bearing more children than they want, even though their desired family size is higher than the national average.

At the other extreme are rural areas of low fertility. Low fertility in this nation since the recovery of the war and postwar years rarely means low to the point of being insufficient for generational replacement. Rather, it is fertility sufficient to increase each generation by a modest increment, say by no more than 25 percent, or less than 1 percent annually. An average of 2,700 children per 1,000 ever married women 35 to 44 years old will do this under conditions of low child mortality and high incidence of marriage. Figure 2 shows the nonmetropolitan countries of the United States in which fertility was less than 2,700 children per 1,000 women in 1960.

U.S. DEPARTMENT OF AGRICULTURE NEG. ERS 5847-69(1) ECONOMIC RESEARCH SERVICE

Figure 2.

Because many metropolitan counties have low fertility, the map has been restricted to nonmetropolitan counties in order to focus on the occurrence of such fertility levels in essentially rural areas. In addition, the map shows those counties in which the white population has less than 2,700 children per 1,000 women even though the overall county average was higher.

The geographic pattern of low fertility is not very blockish, but shows strong representation in the nonmetropolitan parts of the Northeast, central and southern parts of the Corn Belt, the lower Ohio Valley, and the Far West. Unlike the areas of high fertility, it is difficult to characterize the low fertility areas culturally. They are primarily Protestant, other than Lutheran, and include a fair number of future metropolitan counties. Agriculturally they largely exclude the farm areas that were last to be settled or that were not primarily settled by people of colonial stock.

In the South, there is a sizeable group of counties in the North Carolina-Virginia Peanut Belt and some adjoining tobacco counties in which the white number of children ever born per woman is low. I have no suggestion as to why. There is also considerable representation of low white fertility areas in the industrialized Southern Piedmont, the Alabama-Mississippi Black Prairie and in the old cotton area of East Texas. Central Florida is a zone of low total and white fertility.

Although the background of the pattern of low fertility in the areas shown is obscure, the economic significance for each of the areas is that they are under only minimal pressure from the force of childbearing (or, in the South, from white childbearing) for expansion of facilities, services, and employment.

The remaining predominantly rural areas of the country have intermediate cohort levels of fertility that provide substantial population growth or migration potential, but not to the point of resembling conditions in underdeveloped nations.

Migration

On the subject of migration, I should like to discuss three matters—the effects of migration on age structure, the pattern of migration from rural areas since 1960, and a current misunderstanding of the relation of gross migration to net migration.

In rural areas, net migration is commonly the major component of population change. It is also a major determinant of age structure. Outmigration of youth, in particular, has been very high since the Depression. From 1950 to 1960, the rural and predominantly rural counties of the United States that had net outmigration lost 40 percent of their youth who reached 20 years of age during the decade.[3] In some areas, such as the Southern Coal Fields the loss reached 50 percent; and in the poorest southern counties, exceeded 60 percent for Negroes of this age. Such rates of outmovement among the young serve to raise the average age of the remaining population and the proportion of older people, *unless* offset by high fertility among persons remaining and by comparatively rapid outmovement of middle-aged people. Because some rural areas of high outmigration had high fertility and others had relatively low fertility, and because the patterns of middle-aged migration varied by area for a given level of youth outmigration, the overall effect of outmigration on age structure has been quite variable. The popular conception that rural areas were left with hardly anyone except older people after the major exodus from farming and coal mining is all too well approximated in some areas, but is quite erroneous for others. Let me illustrate.

---

[3] Data on net migration 1950–60 by age and color are available in [1].

In the Southern Appalachian Coal Fields the net outmigration rate of youth 20 to 24 years old in 1960 was one third higher than that of white youth in all Southern rural counties of net outmigration, but the Appalachian rate among persons in their 50's was double that of all Southern white persons of the same age (see Table 1). The same differences were evident between whites and nonwhites in rural Southern outmigration counties. For persons aged 20 to 24 in 1960 the outmigration rate during the prior decade for nonwhites was just 20 percent higher than that of whites, but for age 50–54 the nonwhite rate was double that of whites. These age comparisons would be even more extreme if the Southern nonwhite and Coal Fields patterns were compared with Midwestern rural rates.

Table 1. Selected net outmigration rates, 1950–60[a]

Age in 1960	Rural net outmigration counties of the South		Southern Appalachian coal fields (C)	Ratio of:	
	White population (A)	Nonwhite population (B)		B to A	C to A
Years	Percent

55–59	− 5.6	−16.0	−15.2	2.857	2.714

[a] Estimates of 1950–60 net migration expressed as a percentage of the population that would survive to 1970.

Source: [1] and unpublished tabulations from the same project.

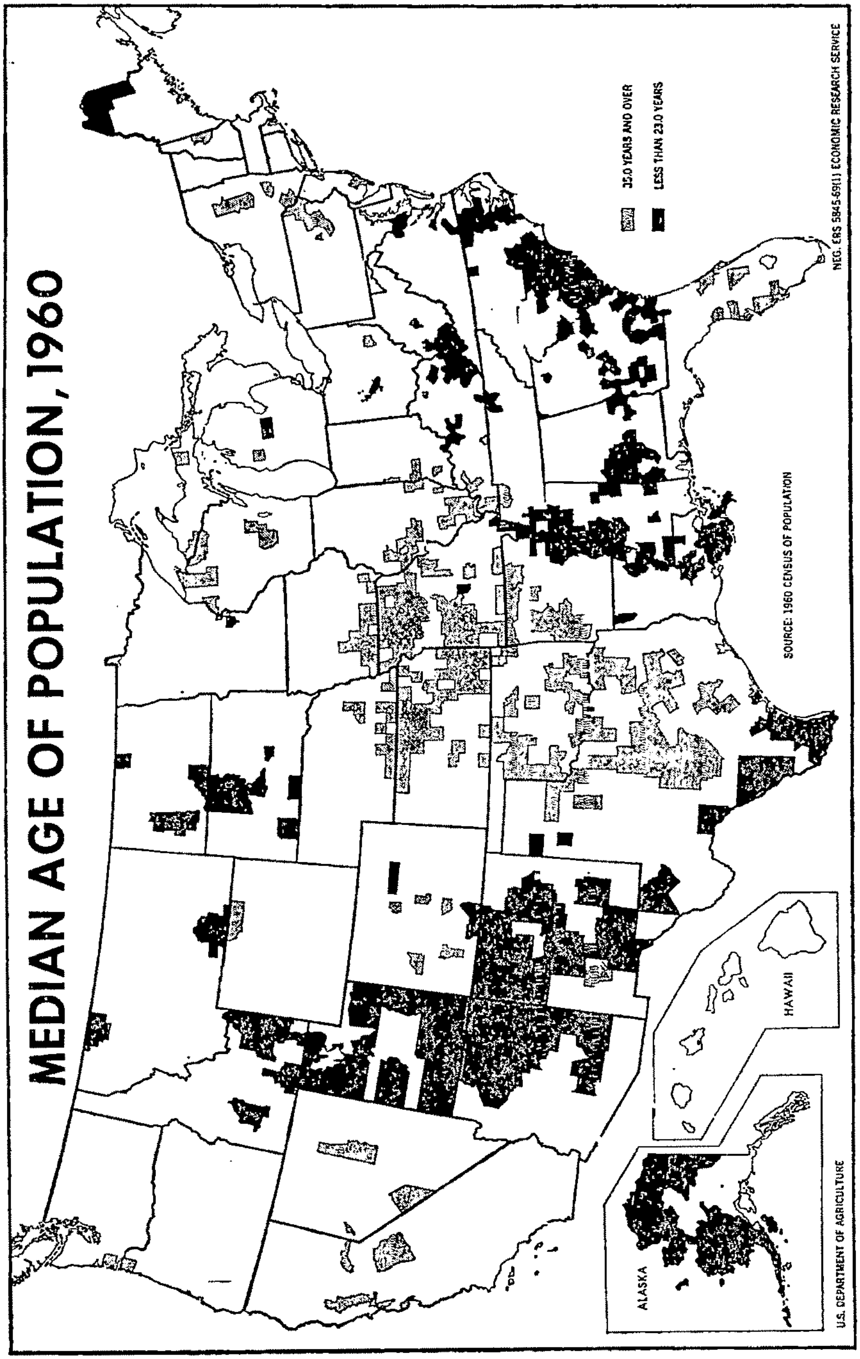
Bearing in mind this point and the previous fertility discussion, note the wide variations in median age of the population in 1960 in the next map (Figure 3). Counties are shown in which the population had a median age of 35.0 years or older in 1960, or a median of less than 23.0 years. Practically all of the counties in both groups are nonmetropolitan. Few of them are even of a submetropolitan character. In other words, the occurrence of extreme age distributions—young or old—in this country is almost entirely a phenomenon of rural and small town areas.

From the Southern Corn Belt extending southward to the Hill Country of Central Texas is a roughly triangular-shaped area of about 300,000 square miles in which the majority of all nonmetropolitan counties, including several large contiguous blocks, have a median age above 35.0. The proportion of elderly people is anywhere from 2/3 to 100 percent higher than the national average. Young adults and young children are comparatively few in number. This is the end result of prolonged age-selective outmigration on a population of low to moderate fertility, here and there abetted by inmovement of older people for retirement while outmovement of the young continues. Elsewhere there are only minor groupings of high-age counties—in the Pennsylvania anthracite area, in relict metal mining counties of the West, in parts of the Upper Great Lakes Cutover area, and in Central Florida. In the latter area it results from inmigration of older people rather than outmovement of the young.

In strong contrast are the counties where average age was less than 23.0 years in 1960. Some of these areas are well known for high outmigration and as a result are misconceived as being of high average age. They include the heart of the Southern Coal Fields, much of the tobacco and cotton coastal plain of the Carolinas, and most of the Black Belt and the Mississippi Delta—in short the worst poverty areas of the South. High fertility and the unusual age structure of migration described earlier have shaped this pattern.[4] Except for the Appalachian group, most of these Southern areas have a median age below 23.0 years only because of the low average age of the Negro population. Indeed, the Negro medians are usually in the upper teens. West of the Mississippi is an area stretching from the Lower Rio Grande Valley to southeastern Idaho where the average age is low. Three different cultural groups are involved—the Mexican-Americans along the length of the Rio Grande, Indians in the Four Corners area, and the familistic but prosperous Mormon population of Utah and Idaho. Finally, the large but thinly settled Indian and Eskimo

---

[4] Higher than average mortality among Negroes in earlier years would also have helped to produce low median ages in the past, but would not be a factor in the failure of the median age to rise in recent years. This same comment would apply to Mexican-Americans, Indians and Alaskan natives.



MEDIAN AGE OF POPULATION, 1960

U.S. DEPARTMENT OF AGRICULTURE

NEG. ERS 5845-69(1) ECONOMIC RESEARCH SERVICE

Figure 3.

areas of Alaska are exceptionally low in average age, as are some Indian and Catholic counties of the Northern Plains.

The economic development problems of the rural areas of very low or high average age would certainly seem to differ in important respects. The young-age areas with a high demographic growth potential require much higher rates of job growth if an objective of their development is the reduction of the necessity of migration. With the exception of the Mormon areas, they are short of skilled and educated people but have a heavy supply of new workers. The high-age areas, on the other hand, with their small families and crushed age structure, are comparatively short of labor force, both presently and potentially. Except for the Southeastern margin of the high-age area the educational level is good, but any significant development of job opportunities would almost certainly require the importation of workers. And each succeeding high school class in these areas is typically smaller than the previous one because of the steadily reduced number of births over the last two decades.

As a footnote on the areas of high average age, it should be realized that most of them either are now having more deaths than births, because of the distorted age structure, or are approaching such a condition. Thus, the population has come to decline from natural decrease as well as from outmigration, and the counties have a new stigma to overcome in promoting economic activity. There were over 300 natural decrease counties in 1966 and the number could rise to 600 by 1970. Nationally, an increase in births is expected by 1970 or thereafter because of growing numbers of young married couples, but the high-age rural areas will not be getting more such couples unless they can retain a far higher percentage of their young people at home than they are now doing.

In the future, it is probable that there will be more rural counties of high average age, and in some areas where they were not found in 1960. For example, from 1960 to 1966, births in nonmetropolitan areas of the Dakotas, Montana, and Minnesota dropped by about 28 percent, creating very rapid undercutting of the age structure in a heretofore rather young population of moderately high fertility.

Population and Migration Trends, 1960 to 1966

Because the Bureau of the Census has now made population estimates for all counties for 1966, we have some means of evaluating change in the population of rural areas since 1960.[5] Estimating population for local areas is less than a perfect science, but the general patterns shoud be valid.

In general, the evidence indicates that completely or primarily rural counties retained their potential population growth much better from 1960 to 1966 than they did in the 1950's. In the '50's the rural counties gained 3.3 million in population while also losing a net of 4.6 million migrants.[6] But from 1960 to 1966, they gained 2.8 million, while their outmigration was reduced to about 550,000, or only a fifth of the annual average loss of the 1950's. Because of lower natural increase, the growth potential of rural areas was less in the '60's, but the areas retained the equivalent of a much higher proportion of their growth potential than formerly. Whereas in the '50's rural counties in the country as a whole had about 150 outmigrants for every gain of 100 in population, since 1960 they have had only about 20 net outmigrants per 100 gain in population. This improvement has been expecially noticeable in the entirely rural counties and those with less than 30 percent urban population. All of the growth of population in rural areas in the 1950's was limited to the class of counties that were 30 to 50 percent urban, but this has not been so since 1960.

---

[5] See [7].

The most dramatic regional shift has come in the East South Central states. These four states, embracing both Appalachian heartland areas and Deep South Delta and Black Belt areas, exported a net of 1.5 million migrants from their rural areas in the 1950's, but only 164,000 from 1960 to 1966. This is an appropriate place to make clear the point that despite the rise of public concern over rural-to-urban migration from the South in the mid-1960's, the force of the trend had been greatly reduced by the time public awareness developed.

The division that has done least well since 1960 in retaining population in rural areas is the West North Central States. These states contributed more rural net migration to other areas than any other part of the country in the 1960 to 1966 period—some 300,000 persons. By contrast, in the 1950's each of the three census divisions of the South had more rural outmigrants than did the West North Central Division. Even so the outflow from the West North Central states is reduced both in number and rate compared with the '50's.

To illustrate recent regional differences in population change more readily, a map has been prepared that divides the counties of the nation into three groups: (1) those that have grown in population from net inmigration, as well as from such excess of births over deaths as they may have, (2) those that increased in population but had some net outmigration to other areas, and (3) counties that declined in total population (Figure 4).

The growth rates of the counties having inmigration vary considerably, but given the close association of economic and population development, most of these areas can be said to have generated more employment in

---

[6] This statistic should not be confused with the fact that the total United States rural population of 1960 was no larger than that of 1950. Some growing rural areas were reclassified as urban in 1960 as a result of annexation to cities or increase in community size.

Figure 4.

recent years than the local labor force could handle. Much of the Atlantic Metropolitan Belt is evident in this respect, and there are many growth counties in the Southern Piedmont and the Middle Tennessee Valley. West of the Mississippi there are a surprising number of inmigrant counties in eastern Oklahoma and northern and western Arkansas, where very heavy loss of population was the norm in the 1950's. Some of the growth here is connected with retirement and recreation developments, and some with the very real progress in industrial employment that has come to this part of the country. But the indicated population turnabout is so dramatic that I find some people familiar with the area skeptical of the level of growth indicated. In Kansas and Missouri, the actual growth level of inmigrant counties has often been small because of the negligible amount of natural increase of population available. The broadest areas of inmigration are found in the Far West, usually in a continuation of past patterns. Inmigration areas are a broad mixture of metropolitan and nonmetropolitan territory, but with the extended influence of many metropolitan regions evident on the map, such as Atlanta, Houston, Dallas, or Minneapolis-St. Paul.

In marked contrast to the inmigrant counties are those that have declined in population since 1960. There are about 1,100 of them, or more than a third of all counties, but this is an improvement over the 1950's when 1,500 counties decreased. Immediately evident is the heavy concentration of these counties in the center of the country. In the east, the broad core of the Appalachians is still visible as a declining region, and there are many losing counties yet in the Southern Coastal Plain, where there is insufficient industry to absorb continued losses from agriculture. But these areas are small in comparison with the vast region extending from the Rio Grande at about Del Rio, Texas, northeastward to the Upper Peninsula of Michigan, west along the Canadian Border to central Washington, and then southeastward to Rio Grande again. In this territory, involving a third of the land surface of the country, the great majority of nonmetropolitan counties, are still in a state of population decline. These declines are typically occurring on community structures that are already affected by past outmigration, and on local population bases and governmental units that are already small both in total size and density. The population losses in this huge area are generally understandable, given such features as the continental climate, the increasingly extensive nature of much of the agriculture, the predominant lack of timber resources, the dearth of sizeable population centers and markers, and the lack of navigable water. But, how long can further population decline continue without impairing the ability of the region to conduct the productive agriculture that characterizes most of it?

Intermediate between the declining and the inmigrant counties are many that have had net outmigration, but have still achieved some population growth. Many of these have previously declined in population and their present status is one of improvement. Some are former inmigrant areas that have lost part of their past growth impetus, while others have consistently been areas of both modest growth and moderate outmovement.

The general national picture that emerges since 1960 is a marked reduction of population loss—and even resumption of population gain—in many areas that have large numbers of the rural poor. This is not a backing up of population, stemming from lack of opportunity elsewhere, for it has occurred during a period of high national employment. The areas now having the greatest difficulty in retaining population are the vast open lands of the midcontinent, plus the mountainous Rockies. Here the mass of the rural population is work oriented, reasonably well educated and housed, and unsaddled with an ethnic minority status; but economic and other attractions are apparently inadequate for population retention in nonmetropolitan areas.

The Relation of Gross Migration to Net Migration

The migration figures discussed have all related to net migration. They do not tell the whole story, but so often we have nothing more to work with. In recent years, two studies commenting on data on gross in and out migration have led to a conclusion regarding the pattern of outmovement from economically distressed areas that has been influential—at least in Washington—in shaping attitudes toward the likely impact of economic development on gross outmigration. I am referring to independent studies by Ira Lowry and by John Lansing and Eva Mueller [5, 3]. They noticed that gross outmigration rates from areas of substantial net outmigration were no higher than those of areas that had net inmigration. Rather, differences in net migration for depressed areas and growing areas seemed to be due solely to variations of the rate of gross inmovement. Acceptance of this broad generalization engenders a rather fatalistic attitude toward the potential for intelligently affecting outmigration. It makes gross outmigration appear to be so powerful and immutable a force that it flows without respect to economic or social conditions and cannot be modified by programs aimed at economic development.

Recently I have investigated the patterns of gross in and out migration in a more detailed manner than was germane to the larger work purposes of the Lowry study or possible from the small Lansing and Mueller sample. Gross in and out migration rates and net migration rates were computed for all of the 500-plus state economic areas for the period 1955 to 1960.[7] The areas were grouped by their net migration rates and mean gross migration rates computed for each group. Two major points emerge from this work that add to our knowledge of the relationship between gross and net migration and greatly modify the overly simplified concept of the relationships inferred from Lowry and Lansing and Mueller.

---

[7] The basic migration data are in [9]. The base population of each area was taken as the 1960 population 5 years old and over, minus residents living in other areas in

1. Gross outmigration rates *are* related to the level of net migration. True, they do not vary as widely as gross inmigration rates, but they are neither uniform nor randomly distributed. The curve of gross outmigration plotted on net migration is a U-shaped curve, gross outmigration rates being highest in areas of heavy net outmigration and in areas of heavy net inmigration. They are low in areas of negligible net movement—in or out. Furthermore, the frequent equality of the gross outmigration rates of prosperous areas of net inmovement with those of depressed areas of net outmovement is not associated with the same factors, conditions, or motivations, and should not be equated in meaning.

For example, the gross outmigration rate from the San Francisco Bay area—a huge diverse prosperous area that is so often touted as one of our most uniquely attractive—was nearly the same as that from the Black Belt of Alabama, one of our more classic areas of rural poverty and racial discrimination. Would anyone maintain that people are compelled to leave the San Francisco area for economic reasons except in the rarest of cases, given the very wide range of occupations and industries and the high wage scale, in contrast to the narrow industrial mix and lack of net employment growth in the Black Belt? Is it logical to equate in their significance for national policy the surface similarity of gross outmigration rates from the two areas? I think not. Many other prosperous areas of substantial gross outmovement prove on inspection to be military or college centers with large temporary populations and resultant high turnover.

2. The second point is that variation in gross outmigration *is* the major component of variation in net migration among areas that have had moderate to heavy net outmovement. This has not been previously understood. Of the difference between 1955–60 net migration rates for areas of moderate net outmovement and areas of heavy net outmovement, about ¾ was caused by greater gross outmovement from the high net outmigration areas and only ¼ stemmed from lower gross inmovement to such areas. Thus, gross outmigration is not as lacking in response to depressed economic conditions as we have been led to believe. And the corollary of this would seem to be that increased economic opportunity in areas of need would reduce gross outmovement stemming from lack of basic employment activity.[8] Changes in gross inmigration only comprise the principal

---

[8] The view that gross outmigration is about the same everywhere and thus that it is not responsive to economic conditions and unlikely to be affected by economic development has been widespread in the Office of Economic Opportunity. An influential staff document prepared in that agency in 1967 based this premise on the results of the Lansing and Mueller study.

determinant of net migration levels in areas of net inmovement or of low net outmovement—areas that those concerned with rural economic development policy are not especially worried about.

Population Change in Small Towns

Another facet of change in nonmetropolitan areas of the country around which there have been conflicting claims and beliefs is the trend of small towns. The fact that the term "small town" has no standard meaning is part of the confusion, for one person may think of places of only a few hundred people when he depicts small towns, while his listener may have a mental view of a place of several thousand population as the typical small town. These distinctions are vital, for the various size classes of small towns have typically fared rather differently in population trends, especially at the lower end of the size scale.

To improve our perspective on small town change, our office has compiled the incidence of gains and losses and the overall population change from 1950 to 1960 of nonmetropolitan towns of 1950, by size class. I am not sure that I have ever heard anyone with an overly favorable conception of what has taken place in the population change of small towns, but overly pessimistic views of an inaccurate nature are common. An example is a statement from an important speech of an official of the U.S. Department of Commerce, who said, "Small towns and villages, under 10,000–20,000 population, are disappearing except as residential or special purpose satellites of larger communities" [4, p. 8].

The facts do not correspond with this viewpoint. More than ¾ of all nonmetropolitan urban places of between 2,500 and 25,000 population increased in population between the last two censuses, and their overall growth (including the minority that lost) was 21 percent, exceeding the growth rate of the United States as a whole. Even the towns of the smallest nonmetropolitan urban class—of 2,500 to 5,000 population—grew by 18 percent, equal to the national growth rate. One might wonder what more in the way of demographic vitality could be asked of them. It is only among places of less than 500 population—which may not really deserve the name town in the first place—that population loss was more common than population gain (57.5 percent of them declined). But even here there was a small aggregate growth of 3 percent, because the gainers gained more than the losers lost.

To be sure, there are regional differences. Nonmetropolitan urban towns in the North Central and Northeastern States did not do as well as those in the South and West. And in the West North Central States there were 1,500 villages of less than 500 people that declined. Possibly because these *very* small places of the Midwest are so numerous, the impression has arisen that most "small towns" are decreasing in population, or "disappearing" or "dying," to use what seem to be the most popular terms. But such places account for only a small fraction of the total population of nonmetropolitan places, and their experience has simply not been that of small urban towns or even the larger rural towns.

It is not contended here that population growth in small towns is necessarily the same as economic growth. Some of the towns—the smallest in particular—have unquestionably had a decay of economic structure even with some increase in population, because of such factors as a larger population of retired age or the ability of people to commute to other communities for goods and services. But it would be ironic, in view of the proven viability of most small urban towns and the larger rural places from 1950–60, under conditions of government nonintervention and of extreme agricultural and other technological change, if they should now, during the present period of discussion of future public policies relating to the location of economic growth, be read out of the future because economists and others either fail to notice or inaccurately observe what has actually taken place in these communities.

The focus of this article is on demographic issues, but in fulfillment of the broader title given it, there are two comments on social considerations for rural policy that I wish to make. It is probably obvious from the paper that I am not an adherent of the "rural-urban-differences-are-dead" school of thought. This is not to deny or minimize the sweeping convergence in elements of life style or growth in rural-urban economic and social interdependence that we have witnessed in our generation. But have differences in attitudes and value systems merged to the point of insignificance?

Perhaps the most relevant research on this question is that of the sociologist, Norval D. Glenn. He has compared available national opinion and behavior polls over time that present data for urban and rural populations separately. The polls cover such subjects as attitudes and practices relating to freedom of expression, religion, childbearing, ideal family size, political affiliations, the role of women, capital punishment, and the regulation of liquor.[9]

For some topics he finds no meaningful rural-urban differences in either early or recent polls; for other factors, the differences are wide. On more than half of the items there has been some convergence of view, but in some cases very little and in others much. In other areas, there has been divergence of rural-urban opinions. Altogether, it is a very mixed bag and does not support a simplistic view that rural-urban social differences are uniformly disappearing or negligible.

On the premise that voting behavior summarizes and reflects in one index a host of social factors, I have examined the returns by counties of the 1968 presidential election. Rural and urban voting *per se* can not be determined, but metropolitan status of counties would seem to be a suitable proxy, for the metropolitan population of the nation is overwhelmingly urban and the nonmetropolitan population is primarily rural. In the election, 70 percent of the total popular vote was cast in metropolitan counties. The metropolitan plurality went to Hubert Humphrey, the losing candidate.[10] His three percentage-point margin over Richard Nixon in these counties was more than offset by Nixon's nine percentage-point edge in the predominantly rural nonmetropolitan population that cast only 30 percent of the total vote.[11] A difference in degree only, but substantial enough to control the outcome of the presidential election. I do not think there is any better evidence to be offered to support the view that important rural-urban differences still exist that must be considered in framing rural economic policy.

---

[9] See [2]. The author is grateful to Dr. Glenn for supplying him with the rural-urban results of the individual polls on which his larger analysis is based.

The Economic Dimensions Of Rural Poverty

E. J. R. BOOTH

I PROPOSE to argue that the basic problem of rural America is substantial poverty that is no longer connected with farming; to insist that the stream of urbanization is not to be easily diverted in spite of our heritage of agrarianism; and finally, to offer a modification of a well-known proposal as a remedy for many ills.

The Agricultural Asymptote

The farm sector of the United States is fast approaching its equilibrium asymptote in relation to the rest of the economy. The facts are simple and even startling to one who last looked at them five years ago. By 1967, as Table 1 shows, the one million successful American farms produced all but 15 percent of the output and wound up with a total family income averaging $14,000. Both the intermediate group (sales $2,500–10,000) and the non-commercial group (sales less than $2,500) were averaging nearly $7,000 per farm family from all sources. It is very clear that these two groups, comprising over 2 million farms are no longer primarily engaged in farming. In seven years, the intermediate group switched its income dependence from farm to non-farm income, and the non-commercial group did more than twice as well as before in non-farm income. Moreover, even the lower end of the farm income distribution is no longer in dire poverty; these families prudently substitute enough non-farm income to replace on-farm opportunities. It should also be noted that in the whole of farming, non-farm sources of income are just as important as farm sources.

Table 1. Recent changes in the distribution by sales class of farms, and income, United States, 1960-67

Sales class	Proportion of item in sales class						Income per farm family					
	Farms		Sales[a]		Income[b]		Farm[c]		Off-farm		Total	
	1960	1967	1960	1967	1960	1967	1960	1967	1960	1967	1960	1967
			Percent				*thousand dollars*					
Over $10,000	21	31	72	85	58	14	3.1	10.6	1.5	3.2	9.6	13.8
$2,500 to $10,000	32	26	22	12	29	16	2.7	2.9	1.7	3.9	4.4	6.8

[b] Total net farm income, including inventory change.

[c] Includes value of housing, home consumption, and government payments.

E. J. R. BOOTH *is professor of economics at the University of Connecticut.*

None of this should be taken to mean that no problems remain for farmers. Clearly, success itself has caused its problems. Underlying the increasing income disparity between regions of our economy[1] has been a trend toward greater interregional farm disparity. The range across the states of total net farm income per farm has widened dramatically over the period 1949 to 1967. In 1949 the range was $8,240–from $946 in West Virginia to $9,186 in Arizona; by 1967, this had increased to $25,422–from $428 to $25,850–between the same two states.

There remain many farms and many regions no longer suitable for commercial farming. In the first seven years of the sixties, farm workers increased their support capacity from 25 persons each to 42 each, and farm family incomes increased by half. But this truly phenomenal increase in farm productivity did not affect equally all regions or all types of farms. Put in a more logical manner, these increased incomes stemmed primarily from favored regions and from the small, but increasing proportion of highly efficient commercial farmers.

There is no reason to suppose that any of the basic conditions for farming have changed in post war years. At retail, the income elasticity of food consumption has fallen to less than one-tenth while price elasticity remains at one fifth or less (see Appendix A). The essentially declining nature of the industry continues as expected. Output processes are still much longer than the average for other industries, and inputs like space, disease, or weather are hard either to control or to predict. Uncertainty continues unabated. The inability of farm managers in most climates to phase their production for increasing returns means that cost reductions must come from new techniques and so more and more specialized machines are idle more and more of the year. When market structure conditions are added to the above list, and the even more inelastic demand, price instability is a certain symptom.

It is clear that farming has adjusted in the post war period in phenomenal style. There is no longer much left of what we used to call "the farm problem." If public support in research and development, price stability, crop insurance, production loans, and cooperative marketing were continued and improved, the commercial sector of farming could fend very well for itself.

The "farm problem" of surplus labor and low incomes is diminishing to the point where a relatively small exodus from the non-commercial sector would bring about something close to parity for commercial agriculture. There are two ways of looking at this residual surplus labor of a declining industry. The first is from the parity income standpoint. Farm family income increased in the sixties from a level one-half that of national family income to nearly three-quarters in 1967. This means that if one-quarter of the poorest families could be removed from farming without much effect on farm output and subsidized out of all income, the farm and the nonfarm sector would come into parity. This means there is at least 25 percent labor underemployment in farming.

---

[1] These trends, reported in [1] for 1948–60, have been reinforced by the data for the 60's.

From the standpoint of optimal labor-capital allocation in farming for the given aggregate technology, the measure summarized in Appendix B is appropriate. From this method, it appears that farming is at most 32 percent in labor surplus. For such a reduction in farm labor, with a concomitant increase of 20 percent in capital expenses, would maximize average labor income from the 1967 net output.

This range of estimated labor surplus proportions, as income figures have already suggested, is much lower than the estimates made during the fifties. More important, the absolute amount of labor surplus, some 1.5 million, is now a very small proportion of our national workforce. In agriculture, this is still a heavy load to bear. In rural America, where generations of farm out-migrants most naturally wind up first and last, the problems are even more severe. But they have nothing to do with farming.

The People Left Behind

I take this title from the report of the President's Commission on Rural Poverty [2] to advertise as well as I can the most incisive and objective report on rural problems that I have seen.

To summarize the findings of the Commission on the existence and location of poverty, a few highlights can be listed to make my second point—that just because there is no longer a farm problem does not mean there is no rural problem:

41 percent of our poor are rural.

60 percent of our poor are in rural areas and small cities.

25 percent of rural people are poor.

72 percent of the rural poor are not on farms.

60 percent of rural non-white are poor and concentrated in a few lowest income counties.

Poor whites are more numerous and more scattered.

Poverty is deeper in the country, with 95 percent of rural poor earning less than $2,000 (adjusted).

The average American woman 40 to 44 years old has produced 2 ½ children. White farm women average 3.7 children and the non-white, 6.4, when family incomes are lower than $2,000.

The rural people who emigrate come in two varieties: young and educated or old and poorly educated. The middle groups stay.

Americans starve in the country. The Southern Regional Council of Atlanta, Georgia, reported in 1967 that "thousands and thousands of children go hungry, go sick, and die a grim and premature death."[2]

These 14 million rural poor are the pool by which advances in urban welfare programs can be quickly diluted. They are spread thin enough not to be heard until they are concentrated in the urban ghetto.

The Urban Advantage

Town is where the money is.[3] This much is clear from Table 2. Two-thirds of our population choose to live in town, and the effect (or the cause, if you prefer) of this decision is a per capita income 12 percent above the nation's average, compared with a country income of 25 percent below. In fact, with only one-fifth of the total population, the seven largest cities of the nation produce 26 percent of its personal income, for a per capita income 28 percent larger than the national average.

The more urban a region is, the better its economic welfare. And time is not curing the disease. If per capita income trends as it has since 1940, town will continue to pull away from country at an average of $25 per person per year.[4]

Table 2. Income share of town and country, United States, 1929, 1959, and 1966

Region[a]	Population[b]			Personal income			Personal income per capita
	1929	1959	1966	1929	1959	1966	1966
		percent			percent		dollars
Megalopolis	20	21	20	33	27	26	3800[c]
Town	57	67	67	76	76	75	3314
Country	43	33	33	24	24	25	2236
		million			billion dollars		
Totals	122	177	196	86	383	580	2963

[a] I call "megalopolis" the 7 largest cities of 1966—New York, Los Angeles, Chicago, Philadelphia, Detroit, San Francisco and Boston. I call "town" all 223 SMSA's of 1966; and "country," the other 2700 odd counties called non-SMSA areas in the language of the Survey of Current Business.

[b] Population computed from income and per capita income, with adjustments for where received.

[c] Approximate.

---

[2] As quoted in [2, p. 5].

[3] Unfortunately, Standard Metropolitan Statistical Areas obscure many interesting divergencies in types of urban or rural areas, but they are the best classifications we have to determine whether a rural/urban balance is being approached.

[4] The trend of per capita income difference between town and country for 1940, 1950, 1959, 1962, 1965 and 1966 was $\bar{Y} = 411 + 24.5T$, $r = .996$. The chance that

There is no evidence that the largest cities are growing faster than the rest of the country. By imputation, it is clear from Table 2 that the middle size towns are where the population and income growth is. This point has recently been emphasized by Dr. Stolnitz [3, p. 191], who notes that the proportion of urban people living in cities of a quarter of a million or more is lower in 1960 than in any other census year of this century.

The important conclusion from the facts illustrated is that the slight urbanization trend is nothing to be alarmed about in itself. This is no surprise when one ponders what a modern city is. It is chiefly a location where economies of scale prevail in all sectors except possibly in the public sector, where transport services are varied and adequate for large scale input-output transfer as well as commuter traffic and where the output complex is, on the average, income elastic so that the aggregate output is growing. It is also true that services are often expensive, but net standards of living are high enough to attract population.

Once cities become established, their comparative advantages are hard to compete against. While it is clear that diseconomies occur in large conurbations, they do not seem to occur until a population size of at least ½ million and they are apparently offset by the attraction of the varied output and job mix.

All in all, it is not surprising that the per capita income gap between town and country people had grown to $1,078 per person by 1966. What is surprising is that cities had not grown faster in size.

Agrarian Attitudes

In the days of Thomas Jefferson, who called farmers "the chosen people of God," agrarianism was a noble system. Perhaps through the 1930's, it was still relevant and helpful as an attitude toward United States society. However, agrarianism died as a useful concept by the end of World War II, and it is time we gave it a decent burial.

The sacred cows still low among us Let me give you a few examples from a pamphlet extolling "Communities of Tomorrow" [5, pp. 5–6]. This idea—of developing modern towns in the country to serve the new needs of land extensive farming and underemployed rural people—deserves better. But this is what it gets and I shall quote, supplying emphasis by italics and comment in between.

> ". . . in 1790, only 1 out of 20 Americans lived in an urban area. Today . . . seventy percent of our people live on about 1 percent of our land. If this trend is *allowed* to continue, 100 million more Americans will, by the year 2000, be stacked on top of the 140 million already in urban areas."
>
> "Our urban centers . . . are congested, noisy and full of tension, sur-

---

any of these constants estimated was zero turned out to be smaller than one in a thousand.

> rounded by polluted air and polluted water, burdened with too many people on relief, many of whom moved in from the country, unskilled, uneducated, and unable to cope with city life. They are also costly."

My comment: People seem to like urban centers, as the last section showed. Perhaps we might not only *allow* this trend to continue but accept it and nurture it—even if U.S.D.A. is not to be involved.

> "In Washington, D.C., the cost for every commuter auto is even higher—$23,000. Contrast this with the $487,000 street department budget for an entire year in Fargo, N. Dak., a city of 50,000, for all its transportation facilities."

Perhaps we should also contrast the state of the streets in Fargo with Washington and the rate at which people move from Washington to Fargo.

> "'A city can get too big simply because the cost of providing services increases out of all proportion to total population growth,' reports Mayor Davis of Kansas City. 'This becomes perfectly clear when put on a per capita basis, which is about $120 a year in Kansas City. In a city twice this size, per capita costs would rise to more than $200 a person.'"

We might first wonder how much it would cost to build a community like Kansas City with over one million population and a production apparatus with an annual output of nearly $4 billion in personal income. One wonders also at what size costs are minimal and if we are talking about the same services when we compare costs. Lastly, it would be helpful in these analyses if we could include some notion of benefits. I had thought that we had advanced to the point where we understood that value has two blades. Perhaps costs are lower in Kansas City not just because of efficiency, not just because of scale, not just because of the type of service offered, but also because demand is low.

Communities of Tomorrow offers these alternatives:

Build towns and cities in the country.
Reverse the population flow to help towns adjust.
Locate teaching and research in the country.
Use the "space, beauty and underemployed people" of the country to expand industry.
Enable country communities *"to hold their young people."*
"Preserve the *maximum* feasible number of family-type farms."

These objectives are curiously reminiscent of the old rural development program. A mixture of new and old attitudes is exemplified by the first and last halves of the list. Just as the RDP assumed local industrialization was a sufficient condition for economic progress instead of just a necessary one, so the COT program assumes about urbanization. We refuse to learn that these passive historical forces are hard to divert, let alone to harness. Not that the country does not need some improvement of its community structure. But it will get it and maintain it only when it can support it. Man did not build cities and then discover they were conducive to economic progress. He created economic progress at transport, resource, and market nodes, and urbanization followed.

Worse than this misinterpretation of the cause and effect relation of regional development is the residual of shop-worn platitudes about keeping the young at home and preserving, or better, embalming, the family-type farm.

Somewhere, sometime, we must start to consider farming as an industry and rural America a residence with only adventitious connections. Somehow, we must abandon our Tung Nut mentality and programs.

Proposed Policies

To consider a set of general proposals for rural economic policy, we can proceed from a summary of conclusions from the facts already displayed.

There is no longer any "farm problem" as we used to call it.

There are many farm problems wherein agriculture differs markedly from other industries and merits help from the public sector.

The trend toward urbanization is not going to be easily modified, if only because it has been so successful and so costly.

Rural poverty deserves as much aid as the more concentrated and thus more demanding urban poverty.

During the next four years it is fairly clear that new programs will have to be substitutes for old programs, instead of additions as in the past.

This last point merits summary expansion. The economy is presently governmentally overheated. Our yearly federal deficit is running at $25 billion at a time when unemployment is almost at the theoretical minimum of 3 percent and prices are inflating at nearly 5 percent. Never before has it been so obvious that fiscal policy has so little to do with maintaining full employment but mainly fulfills the presumed demand for public goods.

The new administration is not likely to encourage the government sector to expand at the increasing rate of the last eight years. (Government purchases, which text books used to tell the young were a constant fifth of gross national product, are now up to 23 percent.) So I conclude that I must limit myself to suggesting substitutions of expenditures.

The following is a partial and very generalized list of some of the main priorities for new economic policies affecting rural America, some of which is still engaged in farming.

Phase out farm income support programs

During the last 3 years direct government payments to farmers ran at over $3 billion annually. The feed grain, wheat, and cotton programs account for over four-fifths of these payments. Although yearly totals vary, a fair measure of their average rate of increase during the sixties would be twenty percent per annum, and the 1969 federal budget calls for further increases.

As is well known, these programs are essentially income-supporting and retrogressive in incidence of benefits. By imputing a value of land resources above what they can be sold for without a program attached, these programs have tended to prevent economic resource allocation in farming. They may also have provided mobility disincentive to low income farmers.

These programs should be phased out gradually over five years to give time for adjustment of the misallocated resources. The yearly reduction of $600 million in gross income would fall mostly on large crop farmers and net income loss would be modified by some reduction in costs. Price effects will be mentioned later.

I have neither time nor inclination to go into the excruciating detail of these programs, which take thousands of men to administer, billions of dollars to finance, sixty pages to summarize in Agricultural Handbook 345, and one-tenth of the 1969 Budget Appendix to account for. Most are hold-overs from depression or war-shortage years. They stand as living proof that man's institutions are immortal, that we seem to be caught in a fable like that of the sorcerer's apprentice, who knew enough to make buckets and brooms do his work but not how to turn them off. I wonder how many remember the reason that Tung Nuts became one of the ten non-basic mandatory price-support commodities, or can recite the history and provisions of sugar legislation—a fine example of our propensity to amend, extend, but never abandon.

Strengthen production and marketing programs

As mentioned earlier, the special market and production conditions facing farm managers have not changed except to become more difficult. Public aid to guarantee production loans and crop insurance plans continues to be needed. The provision by U.S.D.A. and the Land Grant universities of a research and development department for farming still has the best benefit-cost ratio of any public program. One other type of program is to be suggested, but with reluctance because of past experience.

Farmers need marketing control, even if not to the full extent that almost all other industries possess it. Government aid will be required for this purpose to organize and help administer market orders and agreements and price stabilization (*not support*) programs. Farm cooperative and producer associations should have the major decision-making and administrative responsibility for quotas and prices but government help will be needed in many cases for legal, technical, and coordinating functions. The present programs are adequate, but should be expanded to other crops. Present public storage facilities for grain could be used by producer associations for output inventory control programs to stabilize prices. The critical point is to allow producers to monopolize markets to roughly the same extent that labor unions are permitted. This will become easier as farmers continue to specialize and as the numbers of producers of a commodity settle down to a floor.

Poverty programs

The main thrust of economic policy for rural areas should be directed toward the voiceless one-quarter of rural people, the fourteen million rural poor. Poverty programs should be simple, national, and directed toward a unique goal—money for those who lack it. The ways to provide money for the poor are as diverse as Babylon's tongues, and just as confusing. I want to be simple: My proposal is a national, standardized, income supplement program.

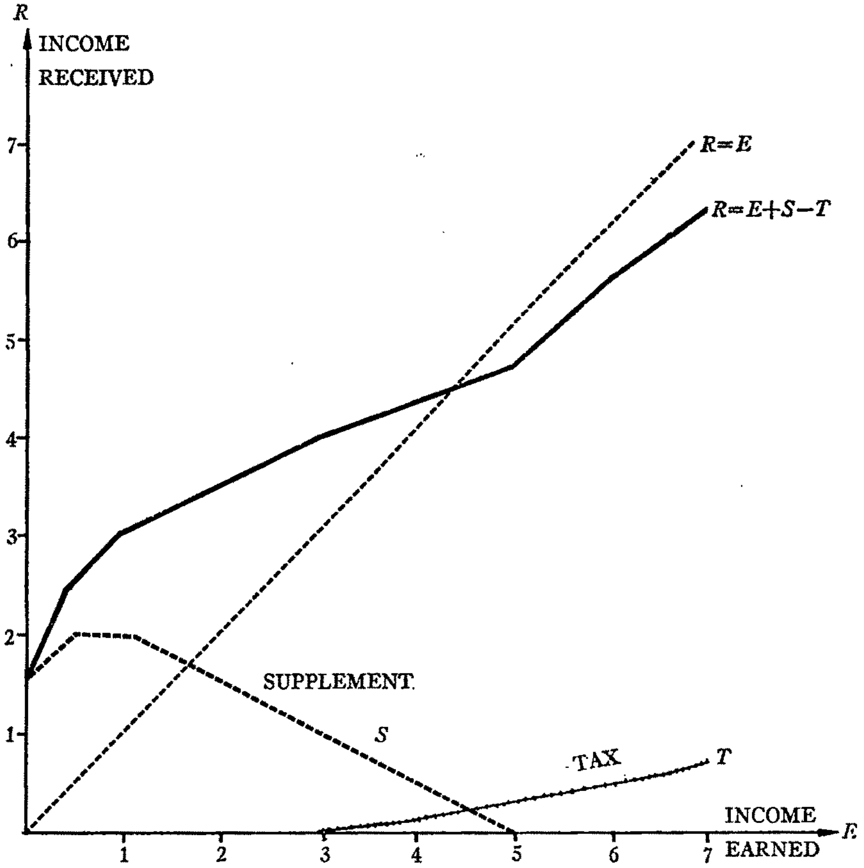
Once more, details must be submerged, but this proposal has been investigated in detail as the negative income tax. What follows differs in one important feature from those which I have read, such as outlined by Dr. Bishop [9, pp. 71–2].

There are two major types of poor family, those with a potentially employable head of family, and those without. For the latter class of families, money for the rearing of children capable of jumping the poverty hurdle is all that can be done. For the former, there is the problem of efficiency or incentive. I propose, that for families with a member capable of work, we define a minimum bare subsistence, a minimum which varies with the size of the family and the cost of living; but for the family of four today, this would be around $1,500. Then, for incentive, the government would add one dollar of supplement for every dollar earned up to $500. For the second $500 earned, the total income supplement would remain at $2,000. Then, as the family earned more than $1,000, the supplement would be reduced by fifty cents for each added dollar earned until supplements ceased at the earned income level of $5,000. Before this level, ordinary income tax would be levied from $3,000 of total income and upwards.

Figure I illustrates the possible ranges of income earned and income received in such a proposal for the typical working poor family. Several special features are worth notice.

The program should be administered by the Internal Revenue Service without regard to residence, occupation, or race, more or less as our federal income tax is now administered. No other agencies should be involved in any way.

Of special relevance to rural-urban balance is the still cheaper cost of living in the country (especially when the family is living on a farm)



(thousand dollars per family)

Figure 1. The income supplement incentive plan

which would mitigate the march to the ghettos. For the "farm price problem," a special provision must be included to deny eligibility to any who produce farm products for sale.

Studies now in progress on the negative income tax should be used to generate information about the wage elasticity of labor supply from poor families and how this elasticity changes as labor supplied increases. The knowledge would aid in determining the optimum level for the "breaks" in the plan (presently assumed as $500, $1,000 and $5,000) and also the level of wage subsidy (now assumed as two for one, one for one, and half for one over the three ranges). But let us stay simple so that the recipients can fill in their income tax forms with no more help than the honest middle class.

The effects of negative income tax on incentive have often been deplored. This is why most proposals include the provision for a gradual reduction of benefits as income rises. But the most difficult thing for the poor to do is to take that first step toward gainful employment. Wages for these people are usually below minimum national standards in occupations where the disutility of labor is high. But doubling their wage rate for the first $500 earned, as proposed here, would tend to balance this disutility; and once a work record is established, the better paying and more rewarding occupations become available. Minimum wage legislation would need to be reviewed to ensure that enough occupations were covered so that the effective subsidy to labor intensive industries is not overdone.

Of crucial importance is to take all the myriad welfare agencies out of this game and to make country benefits more than equal to town benefits, the reverse of which is true of present programs. Benefits would be paid for by those who can afford to, including the rural and suburban rich, through a reasonably progressive income tax.

The total cost of such a plan does not loom very large, compared with other government expenditures. And saving from other welfare plans, including farm income supports, would be expected to equal these costs. For a balanced attitude toward budget allocations, it is well to recall that the federal government presently pays out $13.5 billion annually in interest payments on its debt and, in 1967, was already shelling out 12.9 billion in cash benefits to the poor. It is the distribution of these payments that is so inequitable.

The definition of unemployability is always critical in welfare programs that retain a modicum of incentive. My own predilection is toward the minimum of rules that tend to make the plan work equitably as well as efficiently. Remember that enforcing rigid rules is not only damaging to the incentives and attitudes of the poor but typically costs more than the savings. The problem of the pseudo "broken home" is a case in point. The husband who stays away from home to maximize total welfare benefits also demonstrates that there is a lot of income incentive left among the disadvantaged. To harness this may be less costly than to try to stamp it out. If we should discriminate in any direction, we should make the typical family have the highest payoff and let "unrelated" individuals fend for themselves, with less than they would get as a share of "family" income supplements. The problem of subsidizing the reproduction industry by aid to dependent children should also be faced. A declining scale of supplements for each child over two or three might be acceptable if we did the same for the rich, with declining dependent allowances for income-tax purposes.

Finally, these income supplements should be automatic, regular, and tied only to the completion of an income tax-supplement form sent to all families. Free school lunches, food stamp plans, and special commodity programs should be available up to their presently authorized levels to all who want to use them, but should be gradually phased out. The income supplement plan should be the *only* welfare program for income support.

Employment programs

The best long-run employment program is free school education up to age eighteen. In the short run, retraining programs are most helpful if directed toward job shortages that are likely to occur at the *end* of training. For such retraining programs, I prefer to rely on the people who will use the labor and know best what jobs will be available—private industry. Once again the tax-subsidy approach might be considered. Since no company likes to train workers for its competitors, the government would have to subsidize by a contract to pick up that portion of the costs that industry proved it could not recover.

I am very much against public work programs for only one reason—they do not work. I think that would be fair assessment of the Job Corps. And I am against the Government being the employer of last resort, as the Rural Poverty Commission recommends. This is because, staffed by the efficient civil servant, no government agency is willing to remain only the last resort, even if it were to start that way. Government is already overstaffed. The flavor of handouts and make-work is just what we need to avoid for the poor. If more public works are needed, let them be done in the most efficient manner, with the poor trained to participate like others.

Rural urbanization and industrialization

These programs are clearly not yet major, compared with the size of the problems attacked.[5] The prospect of continuing rural urbanization the way we started rural development is sufficiently frightening to warrant a few warnings. Just as a glove factory placed in a rural area will only prolong the local agony, so the attempt to build an outmoded town of 100,000 in a dying area is doomed. As Professor Wilbur Thompson puts it so well [7, p. 16],

"Small towns will surely survive for a while, if in no other way on the hand-me-downs, the cast offs of the industrial system . . . The farther we go through the system of cities in industrial sophistication, . . . the lower the average age is low, there is a stronger case for measures to stimulate the local economy to take advantage of a highly elastic supply of labor. I have been very sympathetic to this position in the past and my own work reflects this bias. Nevertheless, in all fairness, we should recognize that there may be insurmountable obstacles to successful local development despite the favorable labor supply situation. Skilled labor and management may be in very short supply, access to markets and materials may be very poor, and social services may be of very inferior quality. The point is, however, that we should not rest the case for public intervention on these grounds. The inescapable social responsibility is to assure the healthy development of the human resources which emanate from these high fertility areas. If it can be accomplished via economic development, fine. If not, it must be managed in some other way. We can ignore these areas in which substantial numbers of young people are growing up only at our national peril.

---

[5] In 1967, expenditures and net lending totaled $167 million for area and regional development under the Department of Commerce, of which the Rural Community Development Service managed some $44 million [4]. Small business assistance came to $176 million, and there is no means known to me to sort out the rural component from published data. Water and sewer loans by the Farm Home Administration grossed $175 million. Housing and community development programs spent $577 million, and net lending, including that to support private housing projects, totaled $1.7 billion.

The other point has to do with the implications of these findings for the "urban crisis". We can draw some comfort from what appears to be a retardation in rural to urban migration and the continued viability of small towns. But not too much. Our major urban centers no longer require heavy inmigration to generate the kind of absolute growth which raises serious questions about their economic efficiency and their social stability. The urban problem is here and will not go away even if rural to urban migration ceases altogether. Moreover, given the high fertility rates of Southern Negroes and other rural ethnic concentrations, there is no reason to expect a complete cessation of precisely that kind of migration which has given the urban crisis its most pressing dimension.

Discussion: Demographic and Social Dimensions of Rural Economic Policy

Lee R. Martin

Booth and Beale have presented excellent papers and deserve our gratitude for refocusing our thinking toward important issues.

Booth's paper may be divided into three parts. The first part places rural poverty in context, by identifying the poor and their sources of income and by showing some of the changes that have been taking place in metropolitan (town) and nonmetropolitan (country) areas. The second part argues strongly that improvements in rural welfare cannot (should not?) be achieved by public intervention in the on-going "urbanizing"

Lee R. Martin *is professor of agricultural economics, University of Minnesota.*

process. The third part outlines a poverty program for rural and urban America, as follows:

1. Phase out farm income support programs over five years.
2. Strengthen production and marketing programs.
3. An attack on rural and urban poverty built around the negative income tax. Negative taxes would presumably be permanent for a poor family headed by an unemployable; the incentive provision would be expected to push potentially employable family members toward training and/or gainful employment. Eventually, welfare programs would be dismantled in favor of the income supplement program. Annual costs are estimated roughly, equaling something like Orshansky's poverty income gap ($11.5 billion) minus savings in the farm support program (as much as $3 billion) plus cost of strengthening production and marketing programs (unspecified) minus savings on existing welfare programs (not estimated).
4. Employment programs built around education for youth and adult retraining programs conducted largely by private industry.
5. A modest program of rural urbanization and industrialization, limited to "a few selected already-growing medium-sized cities."

Booth does an excellent job of placing the rural poverty problem in context. He presents only some of the most recent evidence and allows it to speak for itself, which it does dramatically. A little more information on recent changes in the structure of poverty would have been instructive.

I have nothing but praise for Booth's courageous attempt to devise a program that would do something about rural poverty. Few agricultural economists have been willing to make specific suggestions or even to discuss the problem of what to do about rural unemployables. Unequal treatment of rural and urban poor is argued to be indefensible. Reliance upon better basic education as a poverty-prevention measure and upon job-related retraining as a prescription for existing poverty is very attractive.

I must take issue with Booth on his arguments against serious attempts to create more employment opportunities nearer to the rural unemployed and underemployed. I believe he ignores some of the evidence and interprets the considered evidence in an unwarranted manner. Let me summarize my position in a series of statements.

1. Booth seems to base his case largely on a quote from Wilbur Thompson, but his quote does not represent Thompson's statement [1] adequately. The statement is much more balanced and less extreme than the quote would imply. Thompson's full statement [2] provides an even more balanced and thoughtful treatment of the issue of relative advantage.
2. As I read them, the conclusions of Borts and Stein [3] and of Rich-

ard Muth [4] provide little support for the Booth hypothesis, relying rather more on the characteristics of the labor markets to explain differential rates of growth in employment and income.

3. The analyses of rates of 1962–66 employment growth by Haren and Peak [5, esp. Figure 4] and of rates of 1940–60 population growth by Fuguitt [6] do not provide much support for the hypothesis that nonmetropolitan counties are inexorably going down the economic drain.

4. Beale's companion paper also presents cogent evidence on the role of size in economic viability; I will return to this evidence shortly.

5. As Weidenbaum [7] points out, Federal expenditures have large effects on the geographic location of economic growth. The argument that all or even most of these expenditure allocations are closely related to economic (or social?) efficiency does not seem justified. By way of example, the economic growth of California during the 1950's and of Texas during the 1960's seem to have been fed heavily from the Defense Department and NASA budgets. I have found no credible evidence that different allocations of expenditures would have been substantially less efficient.

Mr. Beale presents recent demographic trends that are relevant to economic growth. Two bodies of evidence relate to Booth's arguments. First, between 1950 and 1960, more than three-fourths of all nonmetropolitan urban places between 2,500 and 25,000 increased in population, and their over-all growth was 21 percent greater than the rate for the U.S. as a whole. Second, recent estimates of 1966 county populations revealed that "completely or primarily rural counties did much better in retaining their potential population growth from 1960 to 1966 than they did in the 1950's."

Beale also broke out gross 1955–60 outmigration rates into rates for the 500-plus state economic areas and found, contrary to two more aggregated studies, that gross outmigration rates are related to the level of net migration.

For Booth's consideration, I would offer the hypothesis that, carefully designed and carried out, policies to influence the location of certain types of economic activities toward nonmetropolitan and smaller metropolitan urban centers may well offer one way to circumvent the Phillips Curve. The missing pieces in the puzzle are the costs in efficiency (if any) of such policies, and the reduction in social costs (if any) of a less rapid rate of population growth for large metropolitan areas.

AGRIBUSINESS AND OTHER AGRICULTURAL ECONOMISTS: COMPLEMENTARY, SUPPLEMENTARY, OR COMPETITIVE?

CHAIRMAN: LEONARD J. HAVERKAMP, WILSON AND COMPANY

What Agribusiness Economists Need from Theoretical and Empirical Agricultural Economics

A. C. HOFFMAN

THE land grant colleges have traditionally trained agricultural economists almost exclusively for careers in the agricultural establishment —i.e. for farming itself, for university teaching and research, for service in the U.S.D.A., the Foundations, farm organizations, etc. Recently many departments of agricultural economics have undertaken something new and fundamentally different, the training of economists for careers in business and industry.[1] This may turn out to be one of the most important ventures ever made by the profession.

I want to make it clear at the outset that I think this is a good and commendable thing. But a great deal more is involved than adding a few courses and restructuring the curriculum of agricultural economics to give it some semblance of a business school. It will ultimately involve, I think, a new look at some of the basic postulates and preconceptions of agricultural economics. Put bluntly in terms of the topic assigned me, I think agribusiness economists will need something very different in the way of theoretical and empirical economics than most departments of agricultural economics have traditionally offered. The substantive part of this paper will deal with the specifics back of that statement. But first let's try to get the agribusiness economist and his job in perspective as it relates to his training.

Training Requirements for the Agribusiness Economist

When a business firm plans to market a new product, it usually does some research as to the size, preferences and requirements of the market it plans to enter. And before a department of agricultural economics goes

---

[1] Although there are important differences between corporate and cooperative business enterprises, I think the management methods and problems of both are very similar and becoming more so. For this reason, most of what is in this paper I would regard as applying to both types of enterprise, although on this I defer to the better judgment of Dale Butz.

A. C. HOFFMAN *is vice president, Kraft Foods Company.*

overboard for the training of economists for business, it too should perhaps do some market research for the product it plans to offer.

The first observation to be made is that the market for economists in business is a comparatively limited one. Usually only the larger firms hire economists, and among those usually classified as agribusiness I doubt there are presently more than two hundred positions for economists—only a fraction of the number these same firms have for other types of management functions.

The second thing to keep in mind about business economists is that most of them work in a staff position. These are important and relatively well-paid jobs, but they are not usually classified as upper line management, with the result that as business economists go up the ladder, they frequently transfer to positions in line management for which they may regard their training in agricultural economics as too narrow. Moreover, even in their capacity as staff economists, they are frequently called upon to work on projects involving corporate finance, long range planning, acquisition studies, marketing research, operations research, computer application and other management functions outside the usual range of economics.

What this adds up to is that the agribusiness economist should be trained not only in economics but also for general business management. A corollary to this is that the type of training traditionally offered by our colleges of agriculture and their agricultural economics departments is not, in and of itself, adequate to this purpose. This does not mean that colleges of agriculture should not orient themselves to help in the training of some of their students to enter business, because, for whatever the reasons, that is where a lot of them will end up. It does mean that the training role of agricultural economics departments should frequently be a supplementary one, and they should not seek to duplicate courses and disciplines which are better provided elsewhere on their respective campuses.

Recently some of the members of the Chicago Agricultural Economists Club held a special meeting to offer suggestions for discussion at our session today.[2] You may be interested in their consensus as to the essentials and objectives of training for the agribusiness economist (as given to me by the Club's recording secretary for that meeting): "What we need in the management function of problem solving and decision making is well developed reasoning ability and an analytical mind. The emphasis should be on the development of the capacity for logical and incisive thinking. We should ask the colleges to stress courses in logic and philosophy somewhere in the total academic work of every Ph.D. candidate. It is the quality of the mind that matters rather than the extent of the applied knowledge (which will rapidly become obsolete) of the agricultural society."

---

[2] Members of the Club made many other suggestions that were very helpful to me in preparing this paper, but its shortcomings are mine.

Measured against this standard, the typical undergraduate curriculum taken by most agricultural economists leaves a good deal to be desired. Too much of the course work is narrowly vocational, there is too much orientation toward the physical sciences, and correspondingly too little in the direction of such basic disciplines as the humanities, the social sciences, psychology, communication, mathematics—even a little philosophy as the doctoral degree itself implies. Maybe the best thing a department of agricultural economics can do for its undergraduate majors is to restructure their curricular requirements so they can take as much work as possible completely outside the college of agriculture!

But there are some things which agricultural economists can do better than anyone else, and I think they are very important things. More than most economists, those in agriculture have a tradition for problem solving. Men like Fred Waugh, John D. Black and Ray Bressler were not afraid to take their economics into the market place and apply it to the problems they found there. For the agribusiness economist with problems on his platter, I should think their writings and their methods would be more useful than the esoteric algebraic dialogues on which some of the younger academic economists today spend so much of their time.

A second great tradition of the agricultural economist is that he pioneered, and today leads most other branches of the profession, in the *quantitative* approach to economics. The U.S.D.A. and the land grant colleges have always recognized the need for economic data and provided them. Thanks to this tradition, agricultural economists are without peer in their ability to compile, analyze and present data—and they are the greatest price analysts in the world. These things are of high value to the agribusiness economist.

Within the past decade or so, business has become increasingly interested in computer analysis and operations research as an aid to decision making. Maybe I'm old fashioned, but somehow I distrust these techniques unless they are combined with a knowledge of economics. For this reason I think it is particularly commendable that several departments of agricultural economics—notably Purdue—have added operations research and computer analysis to the analytical arsenal which their students are given. This type of thing is excellent for everyone concerned.

Finally, let's take a quick look at the "raw material" (i.e. the students) for the product you will be offering the business world. To some extent, the increasing number of students electing to take courses in agricultural economics as training for business results from what might be called a surplus of raw material rather than the excellence of the training offered.

When young men from the farm go to college, they have a natural orientation toward agriculture and frequently enroll in the College of Agriculture rather than in some other college or division of the University, even though they know at the time they almost surely will not be returning to the farm. Then as their career plans shape up, many of them develop an interest in business and elect to major in agricultural economics for the somewhat negative reason that its content comes nearer than that of any other agricultural department to the type of training they think they need. This student raw material surplus, coupled with what could be an approaching saturation point in the demand for agricultural economists in the traditional agricultural establishment, may make it a matter of incumbency as well as of choice that departments of agricultural economics begin training more of their students for the business career market. For whatever the reason, I think you are going to be doing more and more of it from now on.

What Agribusiness Economists Need from Theoretical Agricultural Economics

The main theory postulates of agricultural economics are essentially those of classical economics—i.e. perfect competition, an atomistic economic structure, the "scissors," and Adam Smith's old dictum that the hand of the master best fattens the ox. From these postulates, agricultural economics developed most of its economic principles relating to such matters as enterprise scale, selling and price making, capital sources and requirements, and enterprise management. For the most part these principles are appropriate to the understanding and analysis of traditional agriculture and the family farm; but in industry, where the agribusiness economist has to make his way, things are no longer this simple.

For instance, during the past several decades some very fundamental changes have been taking place in the structure of agriculture—(1) the virtually complete transition from farm type enterprises to factory types in the poultry industry, and to a lesser extent in the livestock industry; (2) vertical integration by food and feed companies toward agriculture and even into farming itself; (3) and the sharp growth of the optimum-sized commercial farm, with resource requirements beyond the capabilities of the traditional family farm.

Now these developments were of tremendous importance to agriculture, yet there was almost nothing in the dialogues and researches of agricultural economics to presage them. For agricultural economists with careers in public service, this failure to foresee and participate as economists in these things was not a crucial omission—they were busy with other things and the basic preconceptions of agricultural economics assured that such things weren't supposed to happen anyway!

But what of the agribusiness economist. One of his important functions is to foresee and foretell for his company the direction and degree of change in the structure of agriculture. Imagine his predicament if he had been working for a company which was a supplier to the poultry industry and he had advised it to plan its long run capital expenditures on the assumption that poultry would continue to be produced mainly in farm flocks!

Another postulate of classical economics, which is of less than no value whatever to an agribusiness economist, is that relating to selling and marketing. The classicists did not recognize the function of selling as we know it today in an industrialized, affluent society. Essentially they identified selling as the mere offering of a homogeneous commodity, under what they called conditions of perfect competition, in an atomistic economy. From this it followed that any departure from any of these postulated conditions was *ipso facto* a bad thing from the public standpoint—or more specifically that large-scale enterprise, product differentiation, advertising, merchandising, all selling expenses except those necessary physically to offer and move the produce—all these were either monopolistic, wasteful or unnecessary. This is still the essential position of a large segment of the agricultural establishment, although not so rigidly and universally held as a generation ago.

Now this is not the place to argue the basic issues involved in modern marketing as it exists today in most segments of the American economy. I mention it here because chances are the agribusiness economist is going to spend his life working for big business, and if he doesn't understand and believe in its basic rationale, including its marketing program, then he is going to be very unhappy indeed. I should think he would be well advised to get his training in marketing in the business school across the campus rather than in most departments of agricultural economics.

Perhaps the greatest contrast between industrial enterprise and traditional agriculture is with respect to capital and management. Here again the received doctrine of agricultural economics is at odds with the world of the agribusiness economist.

In agriculture the family has traditionally provided the capital and owned total equity in the farm enterprise. The sources of capital were whatever savings the farmer could make as he climbed the agricultural ladder (if indeed he could climb it at all), inheritance and/or marriage, and the short term mortgage. Clearly and for well known reasons, this system for providing capital is obsolete and inadequate today, and this is the main reason why capital from outside the traditional format of agriculture is now pouring into it.

This new capital is taking several forms and coming from some new sources. Sometimes it takes the form of the agribusiness firm furnishing supplies and equipment to its patrons, sometimes it loans them money, are all three of these things to each other, and there is nothing wrong in this because it is not necessary that we strive for similarity and full accord in all matters. But it is essential that our interests, our priorities and our economic preconceptions *not become so dissimilar that we become in effect two separate disciplines,* each tending to ignore the other and with no basis for common dialogue. There is, I am afraid, more than a little evidence that we are drifting further apart than we should, which is the fault of all of us and to the benefit of none.

Addendum

After I had written my paper up to this point, I let it lie around for a week, then re-read it, made some changes, and decided it needed this addendum.

I have said some rather harsh things about traditional agricultural economics, but I did not mean this paper to be an unfriendly one. I think it is wonderful that agricultural economists are beginning to train students, do research and seek greater rapport with the agribusiness community. I hope that on their part agribusiness firms make the response your efforts deserve, and I hope for the sake of everyone that you succeed.

There are those who will say that any kind of rapport with agribusiness is somehow wrong because the interests of agriculture and those who supply it and process its products are inherently opposed. In some respects and in some situations this may be true, but on balance I think it is not true. Whether true or not, this is no good reason why you should not seek to maintain student training and research liaison with all segments of agriculture and agribusiness. I'm sure you can do it without selling your souls.

What Agribusiness Economists Can Contribute to the Content and Equipment of Agricultural Economics

PATRICK J. LUBY

TO BORROW from famous words spoken by the late President Kennedy in his inaugural address, our President Breimyer has given agribusiness economists a real challenge, "Ask not only what agricultural economics can do for you but what you can do for agricultural economics." As that phrase jolted many citizens eight years ago, this title caused me to look at a few things in a little different light.

For many years, I believe, some of our agribusiness economists have been attending the annual and winter AEAA meetings, have been reading or at least scanning the AEAA Journal, attending other meetings set up by agricultural economists at various universities and drawing information and knowledge from "one on one" situations with their academic and government agricultural economist colleagues. They apparently have found these opportunities rewarding.

While our Association and its economists in public service have set up these opportunities for agribusiness economists and utilized annual meetings and its official publication for the dissemination of knowledge, I know of few similar situations or communications on a formal basis where agribusiness economists have attempted to be the disseminators with the rest of the profession as the principal recipients.

I have reviewed the AAEA Journal for 1966, 1967, and 1968 to gain some insights into agribusiness economists' contribution to the profession by means of its official publication.[1] If my research is accurate and if we define agribusiness economists to include only those employed by private profit-seeking firms, thereby excluding staff members of Federal Reserve Banks, foundations, trade associations and the like, we have had only one article published by an agribusiness economist in the four regular issues. One essay was co-authored by an agribusiness economist. There were also six papers and four discussion papers presented by business economists in the Proceedings issues of 1966 and 1967. Most, if not all, appeared to be invited papers. If we define agribusiness economists to include those of the Federal Reserve Banks, foundations, trade associations, etc., the total rises to over thirty, including those of discussants. (Incidentally, on our

---

[1] For purposes of discussion, I have defined "content" to mean the "total body of thought" contained in agricultural economics, and "equipment" to mean the "tools, methods, and know-how" needed to apply the knowledge to the problems or to attempt to gain new knowledge to add to the body of thought.

PATRICK J. LUBY, *is general provisions manager, Oscar Mayer & Co.*

Association's formal programs, I believe it may be in the role of discussant that the agribusiness economist can best be utilized.)

I did not check to see what percentage of total articles, essays, viewpoints and reviews the above represented. However, I believe it is safe to say that it would be considerably below the percentage of agribusiness economists listed as members of the Association. The latter percentage is not definitely known. In 1967, Dale Butz served as chairman of the Industry Committee of our Association which surveyed agribusiness economists and sent out 325 questionnaires [1]. The membership of the Association in 1966 included 4,157 individuals [2]. This gives us some idea of the proportion of agribusiness economists in our total membership.

This raises the question of why agribusiness economists and especially those employed by commercial, profit-seeking firms do not publish in our Association's Journal. Is it because they have nothing to contribute or because of other reasons, such as lack of time or incentive? Or are agribusiness economists contributing to the discipline by other methods rather than the Journal? I believe they are and will comment more upon that in a moment.

There are, I believe, differences in the incentives to communicate through formal association channels. We have heard much about the probably overemphasized "publish or perish" mandate in universities. Indeed, the public economist is often required to publish the results of his research. On the other hand, it is "profits or perish" in the business world and this may discourage the long tedious procedure required for Journal publications. And if it is highly proprietary information one in business writes about, it is probably "publish and perish" for that individual.

I suspect there are few differences in the time demands of academic and business agricultural economists. Both groups have more problems than time. But I believe that a journal article is looked upon as one of the best uses of time one can make at most universities not only by the writer but also by his superior. I doubt if the same attitudes toward the optimum use of time exists in most businesses. Also, the large supply of bright, young, aggressive graduate students at reasonably favorable wage rates does, I believe, give the academician a sizable advantage over the agribusiness economist when it comes to pursuing problems in depth and reporting on the research in "journalistic" style.

Agribusiness economists and economists-turned-manager may also feel after some years that they are unable to write in the jargon of the discipline for Journal purposes. The writing style exhibited in many Journal articles is quite different from that of business memos or even from most detailed research reports to management in business.

There also may be a basic difference in the preferences between academic and business economists. There is some feeling that the Journal editorial council leans toward articles reporting new research methodology.

It may be that economists who prefer to work at and attempt to extend the horizons of research methodology choose to work in the university environment where the climate may be better suited for such activity. On the other hand, economists who go into business may as a group prefer to use known methods and tools to find new knowledge or apply knowledge already known to real and pressing problems.

Whatever the reasons, it appears that agribusiness economists have not been large contributors to the profession through what is probably the principal means set up by our Association.

However, I do not want to leave the impression that the Journal is the only means by which one can contribute to the content and equipment of agricultural economics. I am sure our many good campus teachers and extension teachers feel they contribute much. In fact, our Association has set up annual awards to officially recognize their contributions.

By the same token, I do not want to leave the impression that agribusiness economists have not contributed to the profession or have deliberately avoided communication with their colleagues. I believe that most public economists who have been responsible for programming conferences, seminars, workshops, and the like have usually found the agribusiness economists receptive to invitations to participate actively as speakers. If one were to review regional and state programs developed by our agricultural economists, I believe he would find a much higher degree of agribusiness economist participation that has been true if measured by our Journal. Sometimes, I sense that there may have been more invitations, except that our university and Washington friends try not to impose upon us and our time. Perhaps this is a delusion. Maybe they have found us unwilling or unable to contribute. Others will have to help me answer this question.

Potential Contribution to Content and Equipment

Apparently the agribusiness economists make up less than 10% of the membership of the AAEA. What can this small group, almost an appendage of the AAEA, contribute?

In the AFEA Industry Committee Study of 1967, about half of the agribusiness economist participation than has been true if measured by our experience in industry. By virtue of their tenure in industry, they have made or participated in innumerable business decisions. Whether managers or staff economists, they have made or influenced courses of direction of firms. As Galbraith pointed out in his recent book, *The New Industrial State*, in today's complex economy, specialists working together as teams form a "techno-structure" which really "makes" the decisions. The economist is usually one of such a group and sometimes organizes and directs the team in problem solving.

Consequently, it is from experience in this environment that should come whatever contributions agribusiness economists can make. To a profession interested in the total agriculture-food complex, this group, representing employment in a sector which is responsible for about 60% of the "value added" to food, should be able to contribute much from its day-to-day living with the problems. This is not to say that others in the profession, by virtue of research and consultation, cannot also contribute. In fact, many do. But agribusiness economists possess a uniqueness of occupation along with a knowledge of the agricultural economics profession which should be of value.

This uniqueness of occupation, paridoxically, does impose a sizable restriction which must be recognized. Agribusiness economists study the motivations and methods by which business policies and decisions are made. They are in a unique position to know for their own firms what these forces are and how they interact in the market. But that knowledge is somewhat confined to their own firms, and the typical agribusiness economist probably hesitates to generalize in print from it for at least two reasons: (1) the observations may not be valid for the total business community (or even for the industry), and (2) to publish the generalizations obviously reveals competitive attitudes, strengths and weaknesses of his firm and may not be tolerable in the competitive world.

Most business economists, agri- and otherwise, are employed by sizable corporations. This is natural and to be expected. Such corporations have the organizations and the range of problems which can justify and attract the service of highly and formally educated economists. Likewise, such corporations are usually found to be in industries which are not very well described by the perfectly competitive model. Therefore, most agribusiness economists are part of decision making in firms in industries which are imperfectly competitive in textbook terms.

For this reason it would seem that they should be of assistance to the rest of the profession to describe, at least in general terms, conduct of management in decision making in firms competing in industries of imperfect competition. Many questions which are not answered precisely in textbooks must be answered daily in business. How are products and markets developed? How are products merchandised? How does a firm try to differentiate a product or service? What is the role of advertising? How does one measure its effects? How does one study the consumer? How does one estimate the effect of a firm's decision to expand or contract capacity on the firm itself and on the rest of the industry? How do firms and industries live with overcapacity for long periods of time?

How do firms plan growth, change, investment and divestment strategies? How does a firm develop an acquisition policy? How are production and processing plants and distribution outlets located? How are joint costs, overhead costs allocated? The role of cost accounting is important for we may have a beautiful pricing system in agriculture, but if farmers, processors or retailers do not really know what it is costing them to produce and market various kinds and qualities of goods, the system will not perform and direct production and consumption in the efficient and effective manner that the theories say it should. How are marginal concepts used in determining pricing procedures, production decisions? What problems occur and how are they attacked in developing international markets? How does or can industry combat rural and urban underemployment problems by plant location, training of the unskilled and hardcore unemployables? These are just a few of what must be many more questions of common interest to all in agricultural economics. It would seem reasonable to believe that many agribusiness economists would have accumulated experience working with many of these questions and problems.

Many agricultural economists have received most of their direct formal training in management with reference to the management of a farm—an atomistic unit whose manager's decisions have virtually no effect upon competitors, the industry or the price received. As time goes on, the management of firms in agriculture appears to be taking on more of the aspects of industrial firms. As this occurs, the insight into the management and behavior of industrial firms obtained by agribusiness economists should be helpful to and utilized by publicly employed agricultural economists. Also, agriculture as an industry is faced by chronic overcapacity problems. Firms in many agriculturally allied industries have also been forced to manage in similar situations. Economists from these firms should be able to report on how industrial management works within such a setting. In what I thought a very convincing manner, Breimyer developed these concepts in a note in the Journal recently [3].

The agribusiness economists grappling with the problems of risk and uncertainty in a complex economy with rapid technological and social change should be producing thought and tools which other agricultural economists can apply to other problems in agriculture, which is in the midst of very similar environmental forces. Many agribusiness economists have become deeply involved in "long-range planning" for their firms in these times of change. To swim in these waters, it would seem that they must develop styles and use strokes which could be shared usefully with economic planners in the public sector.

Other agribusiness economists continue in various fields of economic research. Here they use the equipment acquired in our various educational institutions. While as a group they may prefer to be users of such equipment rather than basically interested in developing new tools, it seems unlikely that these many able, inquisitive practitioners have not out of necessity, if for no other reason, developed new tools or new "twists" to old equipment in performing their duties. Many are employed in the fields of sales forecasting, production planning, product formulation and price and supply forecasting where they have constant need for the best tools available. If our earlier hypothesis is true that the problems and management tasks in the rest of agriculture are taking on more of the characteristics of modern industrial firms, many of the tools developed by agribusiness economists should be of use to others.

It might be argued that many economists "leave the profession" and become managers and therefore cannot and do not contribute. I do not agree with this premise. Many economists from their managerial positions are capable of contributing even more to the body of thought of our profession. An outstanding example of this is the preceding speaker, A. C. Hoffman, active in management for years at Kraft but one of the more frequent contributors in recent years to agricultural economics.

I have tried to develop the thesis that although there are some real problems of confidentiality in some areas of thought and tools, agribusiness economists do have something to contribute to agricultural economics. I have also tried to develop the premise that with some exceptions they have not been contributing as much as they can. It seems to me, for reasons expressed early in the paper, that most business economists are unlikely to use the normal Journal route of communications as a delivery mechanism. I believe that business economists lack the incentives and environment that university people have to publish, especially in our profession's Journal.

Also, it may be that too often in the past, when agribusiness economists have been invited to a platform, they have been invited to participate only to "defend industry's position" on certain questions or have used (or misused) the opportunity and defended a position or argued a case. While such debates may have a very useful purpose in some circumstances, I believe that too often they prevent high level communication of knowledge and ideas.

One of the real challenges of the Association as I see it is to promote useful communication between the two groups. The lack of dialogue in the past may have contributed to or prolonged the apparent polarization of economic philosophies between many public service economists and many of the agribusiness economists.

What can be done to bring business economists more into the mainstream of our Association and make this a more mutual exchange of knowledge is outside the scope of this paper. I believe that the efforts of Dale Butz, Leonard Haverkamp and others during the last five years or so have been steps in the right direction. The annual industry dinner at the summer meetings has given certain identity to industry economists. I believe that if the desire is there on the part of both agribusiness and public economists, a method will be found which will provide dialogue and the mutually beneficial exchange of thought.

What agricultural economics is or what it should be has been discussed at some length in recent years. Added to what it is or what it has accomplished is the fact that it has contributed, along with several other disciplines, hundreds of business economists and managers with advanced academic degrees in industry today. In this paper the arguments have been developed that these people, by the uniqueness of their business experience, have contributed but are able to contribute still more to the content and equipment of agricultural economics. It also appears that this "feedback" is not likely to come through the profession's Journal. The challenge to agribusiness economists to contribute more is a serious one. The challenge to the profession to arrange an effective delivery mechanism for this potentially greater contribution is also serious and would seemingly be open to anyone in the profession.

Discussion: Agribusiness and Other Agricultural Economists: Complementary, Supplementary, or Competitive?

CHARLES E. FRENCH

The profession could have been doing more in agribusiness. Thus, I am sympathetic with the tone of both papers. Yet, I differ substantially with my good friends. My remarks may even sound harsh. Fundamentally, I hope to emphasize the tone they set by criticizing some points.

Agribusiness may be slipping professionally relative to other businesses. Therefore, the tone of this session should be one of alarm.

Dr. Hoffman said we are problem solvers, pioneers, and we do more for misplaced farm kids than other educators. This justifies our existence.

I will not worry much about these two types of economists being complementary, supplementary or competitive. Many complementary and supplementary aspects exist. Competitive relations are trivial. This was

CHARLES E. FRENCH *is head of the Department of Agricultural Economics, Purdue University.*

well established in the great *Saturday Review* discussion in January 1957. Other fine literature has come along since that time.[1]

We may be better at method than at subject matter. I do not understand Dr. Hoffman's thrust: "Agribusiness economists will need something very different in the way of theoretical and empirical economics than most departments of agricultural economics have traditionally offered." Just how different can you get? Our theoretical and empirical economics have not been that far off. We can be criticized for how we do the job, but our basic objectives and notions are fundamentally correct. We advance, modernize, and raise our standards just as an agricultural business does. Criticism of our mode of operation may be well founded, but doubtful relative to our basic intent.

Both talk of our preoccupation with classical economics, family farm organization, internal capital supply, farm management and agricultural science. Hogwash! This is simply not our current type of training. Dr. Hoffman uses structure of agriculture as an example of where we are old fashioned. This area has had an almost repulsive amount of work. We have probably led the economics profession in many aspects of structural analysis. Vertical integration work has moved along. Our students understand behavioral concepts. Planned subsector analyses promise much.

Both speak of management and economics separately. Modern notions with matrix algebra bridge this gap. Ironically, this came in algebra, not in calculus. But it is here. Integration is probably the most catalytic word of this generation. Management and economics will be integrated more.

Subject matter and problem definition are what bother me. Both speakers say we are weak on the demand side. I agree. Dr. Luby gave a most intriguing and impressive set of questions. These we must study.

My plea is for reasonable emphasis on commercial, agricultural, and firm analysis. The AAEA presidential addresses for the last ten years were:

1959 Cochrane — Technology and Farm Supply
1960 Nicholls — General vs. Agricultural Economics
1961 Allin — Price and Income Policy
1962 Brandow — Farm Policy
1963 Hardin — Service and Internationalism
1964 Johnson — Domestic and Foreign Policies
1965 Bachman — Foreign Development
1966 Witt — Food
1967 Bishop — Urbanization and Poverty
1968 Breimyer — Institutionalism

[1] For example, see *National Study on Agribusiness*, Michigan State University, 1961; *Educating Tomorrow's Managers*, CED Report, October 1964; and *Conference on Curricula in Agricultural Business Management*, University of Missouri, 1966.

These say little about firm work. If we drop firm and commercial orientation, we should do it by design, not by default.

Both papers today put emphasis on large companies. Great agribusiness opportunities exist in smaller companies.

We have also become sophisticated. Agribusiness reminds us that they are sophisticated now; we must grow up. We are also sophisticated. We also produce to specifications. Neither company represented here would place an order with any supplier with the uncertain specifications of these papers.

We train from sub-B.S. to post-Ph.D., for line or staff, for staff as transition to line, generalists or specialists, domestics or internationalists, managerialists or operationalists. We are training better men than many agribusinesses are hiring. Also, we may be giving better training than our products get a chance to use.

Dr. Hoffman says there should be better demand analysis for our people. I agree. Both companies and universities would gain. Our students have great curriculum freedom. The problem is not in freedom to take but what to take.

It is popular to quote Galbraith. I would refer to his early work, *The Liberal Hour,* which emphasized the fact that industry should have more influence on our training programs, but certainly they should not dictate them.

Dr. Hoffman mentioned the action in the capital area. Good agricultural economics departments are strengthening their finance areas.

We perform a dual function. We deal in young people. In a sense we are personnel officers as well as educators. Often now, agribusiness personnel officers spend one-half hour or so with our top seniors. They make selections. The next we hear is from a top executive, advising us that he has been trying to hire one of our promising young staff men. Recruiting activities in between are few and far between. The opportunities are many with training concepts, graduate programs, and internships.

Interestingly, our most active cooperative training ventures are with small-to-medium family businesses. Your best technocrats will in many ways be home-grown. But a home-grown apple needs some spraying. We need to get together on the training of company people and on more logical recruiting methods.

Our supply base for young people is much wider than indicated in these papers. The farm boys probably have some assets, but certainly all of our people are not farm boys.

The Chicago Agricultural Economists Club said, ". . . well developed reasoning ability and an analytical mind. The emphasis should be on the development of the capacity for logical and incisive thinking. . . . It is the quality of the mind that matters rather than the extent of the applied knowledge. . . ." This type of man can best be found where only the bright are considered, where theory is mastered, where quantitative rigor is practiced, where written and oral proof is rendered to a group of discerning men who have seen several good applicants previously, where general appreciation for specialty depth and generality of various subject matter exists, where there has been pressure of a long period of hard work which failed to break the man, and where one solid professor can speak from a long tutorial relationship with the man. That is the format of a good graduate program. Here the personnel selection process is sophisticated.

Action exists in this area, but it is not all labeled agribusiness. Good men can be picked up in any good business or agricultural economics program; and additional specialized training, if necessary, is not difficult to acquire. Specific action exists at Purdue, the University of California (Davis), the University of Minnesota, Oregon State University, and the University of Missouri. Companion programs with other departments are available at Michigan State University and Cornell University. Programs or serious discussions exist at Pennsylvania State University, North Carolina State University, Ohio State University, Washington State University, the University of Wisconsin, Kansas State University, Iowa State University, and Louisiana State University. On many programs I am relatively uninformed, but action can be found in many places, and many young men are being sorted out.

We can do much together. Division of labor is not as important as complementary effort. We need more than just critical comments from agribusiness economists. I cannot agree with Dr. Luby to relegate them to paper discussants. We need more than passive use of company data and companies themselves for laboratories. This is great service, but we need more. We need more than agribusiness economists writing in journals. Frankly, I doubt that they will write for journals, nor am I sure they should. Let me hasten to say they should if they wish. The Journal needs them.

The great need is dedication to drive through from theoretical insight to profit-and-loss statement. This takes hard work. Our operations research work has emphasized this.

Some specific possibilities are: (1) Training internships at the B.S. level; (2) Training grants and involvement programs at the graduate level, with some grantor strings to avoid dilution into general school budgets; (3- High-level workshops on problem definition, such as Dr. Luby's list, with a limited number of high-level academic and industry people working hard and openly without this foolish secrecy espoused by some companies; (4) Workshops on method such as some recently successful ones; (5) Research grants with specific terms of time and product so as to allow use of technicians and postdoctorals to expedite the work; (6) Research training grants on problems that accommodate graduate students; and (7) Reminders to each other that education is a continuous process, so both industry and universities will get on the ball with modern approaches, particularly through university adult education programs.

Discussion: Agribusiness and Other Agricultural Economists: Complementary, Supplementary, or Competitive?

DALE E. BUTZ

I believe that Oscar Hoffman has put his finger on the key product that agribusiness needs from colleges and universities—trained and well qualified people. While he has tended to lump training of undergraduates and graduate students together, I am sure that he would agree that there are some very important differences between the training needs of undergraduate and graduate students. For the most part, the undergraduates will be moving into sales, administrative, or other positions, whereas graduate students will be primarily interested, at least initially, in research positions. Too often, graduate courses are merely beefed up versions of undergraduate courses.

I would like to emphasize the point made regarding the need for colleges and universities to research the market for the product they plan to produce or offer. Too often, I am afraid, professors, department heads, or others assume that they know best what should be in the curriculum and how it should be presented, without bothering to research the market. Those college faculties in close touch with the outside world through consulting arrangements, part time extension assignments, or other means, have an opportunity to check whether their course content and their students are geared to meet the needs of today's world. In today's fast changing economy, particularly the agribusiness sector, it seems safe to say that many universities have not really bothered to see whether their curriculum and their students are prepared as well as possible for the job assignments they assume. My personal experience and the comments of my colleagues lead me to believe that the training of agricultural economists for positions in industry is in general less than optimum at most institutions and very poor at many of our Land Grant universities. I believe that most agribusiness economists and executives would be willing to advise on training needs if they were asked to do so.

Dr. Hoffman has listed several major additions to curricula and training

---

DALE E. BUTZ *is with the Illinois Agricultural Association.*

that would prove to be helpful. I should like to add another general area that I believe represents a major weakness in many agricultural graduates, both at the undergraduate and graduate level. I am referring to the ability to communicate in both oral and written form. Very few men or women work in a vacuum. They must communicate if they are to be at all effective. I do not know to what extent good communications are based on innate ability and how much can be acquired. I do know, however, that some skills can be acquired through training, experience, and supervision. In our training programs for agricultural economists, we seem to assume that the degree automatically confers on the recipient proficiency in communication. I believe most of the graduates come up short in this area, and this can be a real handicap in terms of work effectiveness and advancement in the agribusiness sector. Many of those with whom they must work will not be impressed by the depth of the agricultural economists' knowledge if that knowledge cannot be converted into a form useful to the others in the agribusiness firm.

I would like to second Dr. Hoffman's comments regarding the problem solving orientation of agricultural economics. Perhaps I'm beginning to show my age, but it does seem to me that the orientation has swung too far away in some fields from this comparative advantage of agricultural economics. This trend has tended to lessen the direct value of academic research to agribusiness firms. It also has resulted in less close working relationships between academic economists and the business world. Today's university graduates also seem less able to grapple with and solve practical problems.

I believe Dr. Hoffman was a little harsh on the academic economists in assuming that they all stick pretty close to the theory postulates of Adam Smith and other classical economists. Many agricultural economists and many institutions have broadened their training curriculum and research programs to include the dynamics of imperfect competition of the real world.

Dr. Hoffman lists three broad types of research that might be helpful to agricultural economists: (1) case studies in business management; (2) service studies for industry; and (3) broad studies of important problems of commercial agriculture. I agree that all three areas would be helpful, but I have about given up hope of getting case studies or service studies done in time to be of much value to agribusiness. Most universities are not geared to conduct research or publish results in the time span required by agribusiness firms.

I share Dr. Luby's concern over the lack of industry economists' participation in such things as journal articles. While I believe that this may reflect the difference in basic orientation to "publish or perish," I also think that there may be other compelling reasons. One is the fact that many industry economists have difficulty in figuring out how many of the current journal articles can be useful to them in their work. Consequently, they feel ill prepared to put together articles that they fear will not fit the mainstream of the current literature. In addition, they can not afford to spend the time if there is seemingly a good chance that the final product will be rejected by editors.

While I agree with Pat that industry economists have been useful to their university colleagues in conferences, seminars, workshops, and the like, I doubt that the contribution in the area has been as great as it might be. To achieve anywhere near maximum benefit from this type of activity requires, in my judgment, several key ingredients. In the first place, the university staff must sincerely feel that the industry economist has something to offer. Secondly, the industry economist must be willing to devote precious time to assisting in college or university programs. If a close working relationship is established, it would seem to me that the industry economists could be of great value to the university over and above the usual conference or meeting programs. I refer to such things as in-depth analyses and review of the university research program in fields of interest to the agribusiness economist. Another aspect that might be covered is training needs of agricultural economists for business. I have the feeling that many business economists are willing to help if economists in the college are really willing to listen. If academic economists listen superficially and then attempt to refute any suggestion and to justify their position, they will not get much assistance from their industry brothers.

I agree that industry has much to offer the academic economist. The real problem, as I see it, is what kind of a mechanism can be set up to help realize the potential in this area. One possibility, which I believe deserves consideration, is that of some type of business fellowships under which university economists and others would have an opportunity to spend time as full-fledged staff members of an agribusiness firm. I realize there are several such plans in operation now, but most are of relatively short duration. I am thinking of a minimum of six months and preferably a year. This would have to be underwritten by the business firm, but since the university and the individual also stand to gain, they should share in the cost. The venture should be policed so that the business firm or other firms do not recruit the academic person until a reasonable time period has elapsed after his return to university work.

University staff people could gain valuable insight by doing more consulting work. This is not an automatic procedure; such people usually have to achieve some degree of proficiency in a field before they are sought out as consultants. Some institutions and some professors frown on or do not encourage consulting. Apparently they feel that an individual who does consulting work, especially with industry, is in some way a "kept" person. While this is a possibility, it will happen only if the individual lets it happen by compromising his professional ethics.

Another way in which industry economists can be of great value to the profession is by taking an active interest in the affairs of the American Agricultural Economic Association and by maintaining close contact with the departments of agricultural economics in the major territories in which their particular agribusiness firm may operate. If in these contacts both parties frankly express their feelings on various issues, I firmly believe that both the industry and academic economists and, indeed, the entire profession will gain through the exercise. If we remain silent or do not communicate, the profession is likely to be frustrated and divided.

I believe that we have made progress in recent years in the recognition of the industry economists as an integral part of the American Agricultural Economics Association. We all have much to gain from further developing the mutual benefit that can accrue from close working relationships between industry and academic economists. This will not happen automatically since, as Oscar Hoffman has indicated, the trend may be in the other direction. This trend, however, if it does exist, is not irrevocable. If we really take to heart the ideas presented by the speakers here today, we can build bridges of understanding among all segments of our profession.

EDITOR'S NOTE: This section of the *American Journal of Agricultural Economics* may include comments on and replies to previous articles and other literature in agricultural economics, suggestions for improving the effectiveness of the AAEA, discussions of changes in emphasis needed within the profession, and contributions on other topics of interest and importance to agricultural economists. Manuscripts submitted for this section should be prepared in accordance with the guide appearing on the inside of the back cover of this issue and should not exceed 1,000 words.

Communications

CAPITALIZATION OF BURLEY TOBACCO ALLOTMENT RIGHTS INTO FARMLAND VALUES

Capitalization analyses and implications for income distribution have shown that one of the longer-run effects of the Federal production control-price support programs has been the capitalization of the income benefits from allotment rights into higher farmland values (see Clawson [3], Floyd [4], Schmid [8], and Wilcox [9]).

A study at Kentucky, designed to estimate empirically the sale price of burley tobacco allotments and thereby the extent to which the income benefits of the burley tobacco programs are being capitalized into higher land values, indicates that the capitalization of burley tobacco allotments has paralleled that of other types of tobacco and indicates a continuing upward trend in allotment values as yields and prices for burley tobacco have increased.[1] This analysis dealt with sale prices of whole farms and the contribution of the allotment to the sale price of the farm in deriving the estimates of value of burley tobacco allotments.

Five geographic areas of Kentucky were selected for the study, on the basis of the relative importance of burley tobacco to total agricultural income as indicated by density of production. From these areas, all farmland transfers occurring between January 1, 1959, and December 31, 1962, were tabulated from deed records in the local offices of the county clerks. A total of 2,356 farm sales occurred during this period in the areas sampled. After deletion of atypical market transfers, a total of 1,217 usable observations remained.

The data were analyzed by multiple regression procedures according to the model $Y = a + bX_1 \ldots\ldots bX_6$, where

Y = Sale price of the farm in 1957–59 dollars,

---

[1] A study by Maier, *et. al.* [6] in 1960 estimated value of flue-cured allotments by a multiple regression approach. Later studies by Gibson, *et. al* [5] in 1962, Bradford and Toussaint [2] in 1962, and Seagraves and Manning [7] in 1967, using regression, budgeting, and programming, have confirmed the capitalization hypothesis for flue-cured tobacco and have refined the quantitative estimates for values of allotments.

X_1 = Acres of burley tobacco allotment,
X_2 = Acres of cropland,
X_3 = Acres of noncropland,
X_4 = Appraised value of buildings on farm in 1957–59 dollars (logarithm),[2]
X_5 = Location index (average = 100),[3] and
X_6 = Per acre value of burley tobacco production (yield times price) in 1957–59 dollars.

Significant partial regressions were obtained for each of the independent variables included in the analysis.[4] The net burley allotment regression indicated the contribution of an acre of allotment to the sale price of the farms was approximately $3,387 in 1957–1959 dollars. This is slightly higher than the average of $2,985 reported for flue-cured tobacco by Seagraves [this issue] for the same years. However, gross returns for burley were higher than for flue-cured, due to slightly higher yields and prices.

The aggregate analysis was known to contain many observations of small farms that had been bought mainly for the tobacco allotment or had been purchased by urban employees as a place of residence and operation as a part-time farm. Commercial farm operations have allotments mainly between 1.0 and 5.0 acres. For farms with allotments of 1.0 to 5.0 acres, the net regression indicated an addition to farm sale price of $3,689 for each acre of tobacco allotment. All independent variables were significantly related to the sale price of the farm except value of burley production per acre, which approaches statistical significance at the 5 percent probability level. However, on commercial burley farms, value per acre for burley varies relatively little from one farm to another.

Adjustment of the per acre regression estimate for burley allotments to a 1967 basis was made by adjustment upward in line with increased gross returns per acre from burley.[5] Adjustment of the allotment-farm sale price regression to a 1967 basis gave an estimate of $6,015 per acre as the net addition to the price of a farm resulting from an acre of burley allotment.

Costs and returns studies for burley tobacco in the Central Bluegrass Region of Kentucky indicate the net returns to allotment and management at approximately $670 per acre in 1967 [1].[6] This would indicate that an investment of $6,015 in an acre of burley allotment (the regression estimate) yielded a net return of approximately 11.1 percent. Farmers bidding for allotments, in the process of buying farms, apparently discounted expected net returns at approximately double the current rate of interest. The rate of return on allotments would be expected to be considerably higher than current interest rates for two reasons: (1) the necessity for purchasing whole farms in order to acquire allotments, and (2) risks associated with the future direction of Federal programs related to tobacco, including the prospects for future reduction in purchased allotments. Since allotments are purchased only through the purchase of whole farms, the discount rate for net returns (11.1 percent) indicates considerable confidence on the part of producers in continuation of the production control-price support programs in about the present form. This is consistent with uncertainty discount rates for flue-cured tobacco, ranging from 12 to 21 percent (average, 15.0) during 1959–62 [Seagraves, this issue].

---

[2] X_4 converted to logarithms, because farmers tend to bid less than full value for farm buildings when buildings are more than adequate for housing and farm operation.

[3] Location index based on soil type and productivity of the area in which the farm was located, type of road on which farm was located, distance from schools, churches, and other community facilities, and general terrain characteristics of the area in which the farm was located.

[4] $Y = 99.17 + 3386.98X_1 + 96.97X_2 - 16.67X_3 + 1007.21X_4 + 24.17X_5 + 1.47X_6$; $R^2 = .85$; all partial regression coefficients significant ($p < .05$).

[5] Adjustment based on the assumption that land received a constant share of the increase in gross returns from burley between 1959–62 and 1967.

[6] 1958 estimates adjusted for changes in production technology, with family labor valued at $1.50 per hour and land rent at $20.00 per acre. The $1.50 labor cost appears to be in line with hired labor costs and opportunity returns for family labor.

Rental of the tobacco allotment on a cash basis is a fairly common practice in burley producing areas. Generally, such leasing arrangements require that actual production of the tobacco be on the land holding the allotment. Records on cash rentals in the Central Bluegrass Area of Kentucky for 1967 indicate the leasing of some allotments on a sealed bid basis at approximately $480 per acre, with the lessee furnishing all production inputs except the land.[7] An investment of $6,015 (the regression estimate of sale value of the allotment) would return $480 at an approximate 8.0 percent interest rate—somewhat lower than the capitalized net return to land and management, as would be expected in view of the fact that the allotment owner avoids the management input plus any supervisory tasks not identified or allocated as a labor input in budget analysis studies.

The analyses indicated that, at current prices for allotments, a substantial portion of the benefits accruing to producers from the acreage control-price support programs have been capitalized into higher land prices. In the 12 counties for which data were obtained, approximately 3 percent of all farms changed ownership during each of the years, 1959–62.[8] While the original allotment holders were the major gainers of the income effects of the program, purchasers of farms and allotments throughout the history of the burley program have benefited differently. The largest increases in allotment values for flue-cured tobacco have occurred since 1952 [7], and it appears that this is true also for burley. Rising yields resulting from technology have increased the productivity of each acre of allotment for all major types of tobacco, and price supports have maintained tobacco prices that are high relative to all agricultural products. However, as yield-increasing technology has developed, allotments in total have been reduced to maintain supplies of burley roughly in line with manufacturing and export needs. Thus, burley tobacco allotments in the U.S. totalled 250,000 acres in 1967, compared with 374,600 acres in 1940, the first year of price supports.

Summary

Continuation of production control and price supports for burley tobacco over many years has resulted in increased producer returns for this crop.

---

[7] Land rent estimated at $20.00 per acre.

[8] If .03 is a valid probability for transfer of a farm in a single year, then the probability that a farm was transferred during the 35-year period of allotment history (1933–67) is approximately .65.

As producers have come to accept the Federal programs in burley tobacco and to believe in their continuance, the allotment rights to produce have acquired value. When farmland involving allotments changes ownership, a part of the earning value of the allotment is included in the price for the farm. As a result, the new owners do not receive the full price and income benefits of the program.

Analysis of sale prices of over 1,200 Kentucky farms indicated that, in 1957–59 dollars, an acre of burley tobacco allotment added approximately $3,689 ($6,015 in 1967 prices) to the sale of the farm. Estimates from regression are consistent with allotment returns from cash rentals and from discounted net returns and are consistent with estimates of allotment values for flue-cured tobacco, the other major cigarette type of tobacco produced in the United States.

CREDIT IN THE PRODUCTION ORGANIZATION OF THE FIRM: COMMENT

Professor Baker [1] has provided some useful insights into the effects of credit use on farm organization. Because of the unique manner in which credit charges and lenders' attitudes affect resultant input costs, credit use may cause the optimal product mix to differ substantially from the norm of the internally financed farm. Indeed, the optimal farm organization may differ widely even among farms using credit, depending on the source of credit and the lenders' appraisal of the borrower.

The essence of Professor Baker's article is that, because of the manner in which the credit market enters the farmer's decision-making framework, the farmer is not a pure competitor in the input market. The implications of this are many. For example, neglect of explicit credit sources may introduce errors into normative analyses, such as farm planning and supply response studies. Input prices and quantities may not be predetermined, as is often assumed in aggregate studies, but may be determined during the growing season by credit supplies, lenders' expectations, etc. In general, any studies involving the assumption that farmers are pure competitors in input markets may be affected.

Professor Baker concludes that we need to know the characteristics of the credit supply functions of lenders. However, because of the important implications of his findings, it would seem to be of some interest to investigate the *a priori* conditions under which the credit supply functions will not cause a shift in resource use from the norm of the internally financed farm.

The firm is assumed to be a pure competitor in the input markets, but must finance the purchase of inputs. Cost of variable inputs is thus given by

$$C = u(1+i) + v(1+j)$$

where $u = p_1x_1$; $v = p_2x_2$ and i and j are the interest rates which are determined as some functions of u and v, respectively. C can be interpreted as a credit limit. One of the necessary conditions for cost minimization, given a specified output level, is in this case

$$(1) \quad -\frac{dx_1}{dx_2} = \frac{p_2[1+j+vj_v]}{p_1[1+i+ui_u]}$$

where j_v and i_u are the derivatives of j and i with respect to v and u, respectively. (The credit supply functions are assumed to be monotone increasing with continuous first derivatives.) Only when the bracketed terms in (1) are equal will the credit user have the same minimizing solution as the internally financed firm. Under what conditions can the bracketed quantities be expected to cancel?

First, suppose the lender is completely indifferent to the type of input purchased and regards interest only as a function of total credit extended. In this case, $z = u+v$, i is identically equal to j and is a function only of z, the derivatives are also identical, and the bracketed terms cancel. This presumably represents the case in traditional theory in which borrowing does not affect input allocation.

The next simplest case would be one in which i is a function only of u and j only of v. This might occur because the loans are self-liquidating, because of different sources of credit, etc. In this case, cancellation requires that $(j + vj_v) = (i + ui_u)$. Thus, even if i and j were equivalent algebraic functions of u and v, respectively, the two terms would cancel only if $u = v$, that is, only if the farmer were to purchase the same total of each input. For n inputs, he would have to spend $1/n$ of total credit on each input. This type of symmetry is not to be expected in general. When the credit supply functions are not identical, the conditions for cancellation of the brackets become more complex but appear equally unlikely.

It is probably more realistic to suppose i and j are not independent functions of u and v but rather that i and j are each functions of both u and v. In this case, the necessary condition under discussion becomes

$$(2)\quad -\frac{dx_1}{dx_2} = \frac{p_2[1 + j + vj_v + ui_v]}{p_1[1 + i + ui_u + vj_u]}.$$

When the cross-partials, i_v and j_u, are zero, (2) becomes the same as (1). When the cross-partials are not zero, they appear to offer no increased hope that the use of credit will not affect resource allocation. Again, even if the credit supply functions for i and j were identical, the terms would cancel only when $u = v$. When the functions are not identical, there appears to be no generalization that will insure, *a priori*, that the allocation of resources will not differ with credit use.

When the lender reacts to the farmer's credit requests by varying the loan limit, the situation is equally bleak. The cost is then given by

$$C = du(1 + i) + bv(1 + j)$$

where d and b represent the rate at which the lender reduces the farmer's loan limit. d and b can be constants or may be functions of u and v. In the latter case, d and b will enter the minimizing conditions in a manner similar to that described above for i and j as functions of u and v. Even when constants, d and b will enter (2) as follows:

$$-\frac{dx_1}{dx_2} = \frac{bp_2[1 + j + vj_v + dui_v]}{dp_1[1 + i + ui_u + bvj_u]}$$

so that even the existence of identical credit functions and equal division of expenditures between x_1 and x_2 will not insure cancellation of the bracketed terms.

A cursory examination of the necessary conditions for the allocation of two inputs purchased with the use of credit suggests that credit use can in general be expected to affect the allocation of inputs. A detailed investigation would require much more space than available here, even without dropping the naive assumption of monotone continuous credit supply functions. However, further investigation under more complex conditions would probably reinforce the conclusions of this note. Thus, Professor Baker's article is indeed extremely relevant to research in farm management and production economics.

TOWARD A CONCRETE CONCEPT OF EFFECTIVE COMPETITION: COMMENT

In a recent provocative article [5], Professor Stephen H. Sosnick specifies operational performance standards of effective competition. The article has much merit, but some additions and revisions seem necessary to achieve the objective of developing useful performance standards by which real markets can be judged.

1. An essential of effective competition, relegated by Professor Sosnick to only two words in a footnote [5, p. 842, footnote 21], but stressed by

(presumably as necessary conditions of effective competition) "increasing diversity in the structure of production and consumption," "new products and processes and improved institutional arrangements," and "wide diffusion of the benefits of progress." None of these criteria appeals to me because none is definite. For example, in a Sacramento supermarket the number of different brands, types, and sizes of 14 commonly used grocery products[1] increased from 17.6 per product in 1962 to 20.4 in 1968 [1, p. 41]. Whether this increase in diversity satisfies Dr. Pritchard's norm is not clear, since he does not state what kind or amount of increase in diversity he requires. Similarly, a demand for wide diffusion of the benefits of progress will not be definite until it is explained how to decide when the amount or duration of profits has exceeded what the record of innovation justifies.

I have another objection to demanding increasing diversity of products. More diversity (unlike more progress and, perhaps, unlike wider diffusion) is not, in my mind, necessarily or even usually preferable to less. Increasing diversity ordinarily increases the costs of production and distribution. It may also add confusion. To illustrate, Consumers Union sent five women to buy the 14 staples mentioned above. The women were instructed to disregard quality and to select the package that offered the lowest per-unit price for each of the 14 items. Despite spending an average of 50 minutes in the store, the women, all of whom were college educated and regular shoppers for their families, made incorrect choices on 38 out of the 70 opportunities. In 1962, a similar group of women took less time (43 minutes) and made fewer incorrect choices (34 out of 70). Because both confusion and costs increase with product diversity, diversity may be excessive as well as insufficient.

Is there an acceptable criterion of excessive diversity? One might say that diversity is excessive if there is a variation that no buyer finds useful, or if the variations have been carried beyond the point where the extra diversity is worth the extra cost to buyers, or if a reduction could be made that would improve the position of some people so much that they would be better off even if they had to compensate everyone who would be worse off. While I find these criteria acceptable, none seems to be definite, and I can think of no acceptable alternative that would be usable in practice either. That is why I mentioned product diversity only in passing.

To have no specific criterion concerning product diversity, however, is not really to ignore the subject. The trouble in the Sacramento supermarket is what I characterized (page 849) as "information less complete, reliable, or available than would maximize a measure of traders' collective gain from trade in the market, net of information costs." In particular, the trouble is, as Consumers Union points out [1], lack of per-unit pricing (except for meat). Without per-unit pricing, many consumers apparently cannot even rank prices, let alone evaluate different price-quality combinations. With per-unit pricing, equilibrium with perfect competition. But to phrase the question in terms of what imperfections are tolerable implies that the structure, conduct, or performance attributes of perfect competition are desirable, that closer approximations to them are preferable to more distant approximations, and that the relevant task is merely to decide how much deviation is normatively acceptable. And none of these implications is acceptable. E. H. Chamberlin and J. M. Clark have explained the defects of the first two implications. As to the third, I tried to explain (page 839) why introducing tolerances creates trouble; tolerances are arbitrary, and to adopt them invites labeling a situation *effectively competitive* even though it contains removable defects. Accordingly, I see only problems arising from viewing the objective to be the identification of acceptable degrees of imperfection.

I may, however, be wrong, and I hope Dr. Pritchard will undertake to present, full-scale, his own concrete concept of effective competition.

QUADRATIC PROGRAMMING SOLUTION OF COMPETITIVE EQUILIBRIUM FOR U.S. AGRICULTURE: COMMENT

The authors Hall, Heady, and Plessner make these comments in the final section of their article [1, p. 551]: "This equilibrium study is only the first phase of a larger study. . . . Our aim is toward the rather long period required to make models of this type completely operational . . . We hope, as work progresses, to incorporate improvements in both the data and the model."

Their present reports seems to be premature, however, and the empirical results misleading. Publication of the article might be justified by its potential usefulness as a classroom exercise in econometrics, but why pretend or imply reality when so little is actually present? We have no particular quarrel with the objectives or model used in the study. This comment is rather a plea for reality in empirical applications and results. If an article's value is largely in its methodological content, that ought to be made clear to even the most casual reader.

It appears to us that the authors did not conduct an adequate inspection and evaluation of the results of the computer optimization. If so, how did they rationalize:

(1) the magnitude of the differences in farm prices reported for the several consumption regions of Table 3, and

(2) the apparent difference between 1965 actual and optimal soybean yields of approximately 67 percent?

It seems entirely fair to ask, too, how three economist authors and several probable reviewers could have permitted the following statement to stand, namely: "This special treatment of cotton was necessary because cotton lint is not a final product, and, thus, there are no demand functions for cotton" [1, p. 541]. Of course there are demand functions for cotton—cotton growers have sold cotton for many years at various prices! We have no objection to the deletion of cotton from the analysis, but the stated reason for doing so is improper and unacceptable.

With respect now to question (1) above, a case in point: Wheat for food use is shown in Table 3 to have a farm price of $0.48 in region 8, and $1.02 in region 9. Regions 8 and 9 are adjacent to each other. The difference in prices is $0.54 per bushel—what ordinary mode of transportation would involve rates anywhere near that level? Or is the optimum solution in violation of restraint II. 5. [1, p. 540], which requires that prices in any two regions cannot differ by more than the costs of transferring the grain from one to the other?

Question (2) relates to some of the data of Tables 2 and 4. Soybean acreage actually harvested in 1965 was 34,450,000 acres (Table 4), and actual U.S. demand for soybean oilmeal, including exports, was 13,450,000 tons (Table 2). This is an apparent gross yield of 0.390 tons of soybean oilmeal per acre. The same calculations applied to the estimated 1965 optimal solution implies a yield of about 0.652 tons of oilmeal per acre, an increase over the actual yield of about 67 percent. Are we to infer that land available for crop production is presently that poorly allocated to the production of the field crops included in the model?

These two specific references to the empirical results of the Hall, Heady, and Plessner study illustrate our point: That within the profession there may have developed a predilection to substitute methodology, models, and computers for good economic rationale, and to ascribe to them powers beyond their limited, mechanical capacities to aid in the analysis of data. Analysis should not end with the computer read-out. Computer solutions ought to be inspected closely for their adherence to reality as well as to the mathematical assumptions and restrictions of the model.

It is not easy to visualize how a comprehensive general equilibrium model of the crop or livestock-crop economy could be developed to the degree necessary to evaluate adequately the probable effects of alternative policies. The quantitative detail necessary to approach reality; the complex interrelationships in production, processing, and distribution; and the heterogeneity of products and factors critically limit the usefulness of any such complex model for policy purposes. The departures from reality necessary to make the model operational can, and in this case apparently did, yield results which, if followed by farm policy decision-makers, would be seriously misleading.

[1] HALL, HARRY H., EARL O. HEADY, AND YAKIR PLESSNER, "Quadratic Programming Solution of Competitive Equilibrium for U.S. Agriculture," *Am. J. Agr. Econ.* 50:536–555, Aug. 1968.

QUADRATIC PROGRAMMING SOLUTION OF COMPETITIVE EQUILIBRIUM FOR U.S. AGRICULTURE: REPLY

The comment of Messrs. Smith and Purcell may be regarded as consisting of two objections: first, it questions the usefulness of employing quantitative models in economic analysis because of their "... limited, mechanical capacities to aid in the analysis of data." This, *vis a vis* the immense complexity of the real-world structure to which such econometric models are applied. Secondly, the comment questions the likelihood of some specific results presented in our article.

With regard to the first point, there is nothing novel in observing that the real-world complexities do not diminish if one does *not* use simplifying quantitative models. This does not imply, of course, that results read off the computer printer can, or should, be implemented, at least not before they are carefully screened. This, however, is not the issue. The judgment on the value of a publication such as ours is not (or should not) be a function of the precision with which the model reflects reality. It is a function of the extent to which the application of the model contributes to the understanding of real-world phenomena and processes. It also depends upon the usefullness of the model as a means of enhancing the effectiveness of "good economic rationale." This last role is fulfilled precisely by the simplifying nature of models. For even the most brilliant mind cannot simultaneously analyze the entire spectrum of events and causes present in the real world.

In addition, we fully recognize that an application of our model will be "mature" and exhibit its full capacity only after a considerable refinement of the data used and the assumptions employed. This, however, is no reason for withholding from the profession the information on the progress made so far. Of no less importance than the actual results obtained at this stage of the research is the potential usefulness of the approach. Our article makes this very clear.

Considering the specific questions of the comment's authors, the answers in both cases lie with the data. The difference in wheat prices in regions 8 and 9 is $.54. The transportation cost between these regions is $.84. This results from our assumption that demand and supply in each region are concentrated in one point in space. The use of historical average freight rates, rather than our normative rates, might have been preferable.

As for soybean meal, our *normative* data indicate a range of yields per acre from .28 tons (region 70) to .90 tons (region 134) [see map in 1, p. 545]. A yield of .65 tons falls well within this range. We might add that the arithmetic mean of yields in all regions is .56 tons. Apart from the explanation, we want to emphasize that a deviation of 67% of the programmed yield from its actual counterpart is not, *per se*, a reason for rejecting the results. First, the results also indicate an accompanying drop of 33% in price. This would constitute a major incentive for concentrating production in relatively high-yield regions. Secondly, the imposition of perfect competition on the system is itself a major deviation from the real-world situation, and is thus liable to produce some major deviations in specifics.

Finally, we did not intend to imply that ". . . there are no demand functions for cotton." What we did mean is that, since cotton is an intermediate good utilized in numerous and very different final goods, no satisfactory estimates of demand functions for cotton are available. We agree that the wording of our statement leaves something to be desired.

We hope that our present reply makes quite clear what should and what should not be attributed to our model. We hope that in the near future we shall be able to present a more detailed description of possible uses of the model in the formulation of policy.

We are not completely "immune" to the real world. We did not include livestock either, but we were not assuming that these products had "no demand." The same is true for grapes, oranges, apples and other commodities not included in the model and calculations. We were largely making a methodological illustration and application in this report. We believe that we emphasized this fact amply, although we did put more statements to this effect in a longer initial draft of the report, shortened to meet space requirements. In our article, we indicated that the report was one phase of a larger study. We have found it extremely difficult and complex to get a computer program which is applicable for large problems. At the time we write this, we are still after the "bugs" which restrain us on large models. If Smith and Purcell rush to our aid with armloads of coefficients, including demand functions, and computer programs that both work satisfactorily, we can soon get solutions to extremely extended models. In the meantime, we must slave away at the very large task of assembling and synthesizing sufficient data and improving computer programs that will allow us to get solutions of medium-sized problems. As soon as we complete this step, we shall turn to larger and more complete models. Still, we wish they would rush to our aid with the data and the efficient algorithm. In the meantime, we believe our first numerical application suggests the utility of such models and our first stage efforts.

Reviews

Butterwick, Michael, and Edmund Neville Rolf, *Food, Farming and the Common Market,* London, The Oxford University Press, 1968, xiv + 259 pp. ($7.75)

This volume is an assessment of differences in conditions and policies in the U.K. and the EEC and the effect on the U.K. that will follow from entry into the EEC. "The general objective of the book is to bring together, for the benefit of interested people in the U.K. and the community, information about food and farm policy, farming, and the ancillary trades and industries, here and in the EEC" (p. xi). This objective is followed. A great deal of information is presented, and it is aimed at an audience that has a degree of pre-acquaintance with European policies and conditions. In the relatively short space of 219 pages, the authors cover (1) formulation of EEC and U.K. policy (Chapters 1 and 2); (2) the impact of U.K. membership as it would influence balance of payments, retail food prices, U.K. trade in agricultural products, the cost of five categories of farm inputs, prices, and incomes, the future of marketing boards, agricultural cooperatives and ancillary trades and industries (Chapter 3); (3) both negotiations in Brussells (Chapter 4); and (4) the situation for 12 different commodities or commodity groups (Chapter 5 through 16). Doing this means that they have not used much space to lay out background conditions or the detailed workings of existing agricultural policy. As a result, some readers on this side of the ocean, at least, will be left wondering about such things as what the British standard quantity system is and how it operates, and what is involved in the French system of Producer Groups and Agricultural Economic Committees. Though gaps of this kind will exist for some readers, it is not a criticism of the book. The authors clearly did not intend to write a volume that covers all of U.K. and EEC agricultural policy.

The study is an investigation of the political-economic interrelationships involved in adapting U.K. policy to EEC policy. In some cases, exhaustive detail is presented on items that are not normally of central importance in agricultural policy while other apparently more important items are covered with a great deal less detail. As an example, the chapter on pigmeat covers only 5 pages while that on eggs covers 21 pages. In part this reflects the amount of information available, but it is also a reflection of differences in the complexity of the issues that will have to be faced in negotiation and in adaptation by the U.K.

While much data is introduced throughout the volume, there are very few tables included in the text and no precise quantitative projections will embarrass the authors in the future. When quantitative estimates of change in price or other variables are made, the authors either content themselves with quoting other persons or with stating their own estimates as general orders of magnitude. Despite this lack of precision in their quantitative analysis, it is apparent that they have a considerable degree of insight into the economic consequence of joining the EEC. Further, the book conveys some of the political subtleties inherent in this kind of change, both in relation to domestic British agriculture and in relation to bargaining with the EEC.

The book has one weakness: the authors don't tie the details of their analysis together. No chapter summaries are included, nor is there a summary chapter. The reader, thus, is left with much information and analysis but without a clear general picture of the probable effects of U.K. entry into the EEC. For this reason also, the book will be more useful to persons who have some acquaintance with European conditions and want more information on the specific issues and problems involved. This will include, in addition to Europeans on both sides of the channel, many persons in other countries who have a direct research, trading, or policy interest in the effects of enlarging the EEC.

Doll, John P., V. J. Rhodes, and J. G. West, *Economics of Agricultural Production, Markets and Policy*, Homewood, Illinois, Richard D. Irwin, Inc., 1968, xiii + 557 pp. ($8.50)

Each time a principles of agricultural economics book is published, those who teach introductory courses, probably like me, hope it will be just right for the introductory course. This is not that book. As the authors state in the preface, their book "treats some of the more important parts of agricultural economics at the next level past principles."

However, some needs in an introductory text seem relevant to this review. An introductory text should above all improve the economic literacy of its readers who are majors in production departments, agricultural economics departments and even in departments outside colleges of agriculture. To accomplish this, it must provide a vivid and accurate description of the role of agriculture in an economy (state, nation, world) and to demonstrate the relevance and application of economic principles to problems of agricultural production, marketing, and consumption. It must be simple and empirical enough to interest the most traditional production-oriented student, yet analytical enough to provide an effective building block for the pre-professional economist.

Although that standard is most difficult to achieve, *Economics of Agricultural Production, Markets, and Policy* fits the standard well. However, it cannot be used as an introductory text because, as the authors state, it presents information at an intermediate level and emphasizes economic theory. Most comprehensive principles courses are offered at the introductory level, not at the intermediate level. It will be a useful text only in departments that emphasize preparation of undergraduates for graduate study and offer a comprehensive intermediate agricultural economic theory course. Unfortunately, because of the organization of course offerings, the effectiveness of this well done text will be largely restricted in undergraduate teaching to use as a theoretical supplement to specialized texts in farm management, marketing, and policy. Perhaps its publication will encourage departments to offer a general course for advanced undergraduate agricultural economics majors and for non-major graduate students in either general economics or other agricultural fields.

The beginning graduate student who has had very little economics, or one who needs a comprehensive review of theory early in a graduate program, should find it most useful. I know of no other modern single source review that so fully covers the field of agricultural economics.

The book is particularly well written and edited, which should increase its acceptability among discerning students. Its general organization is good, except that material in the last chapter would, have greater relevance near the beginning of the book. It would enable students to see the usefulness of theory in solving economic problems in agriculture before they study theories. I wish the authors, all of whom I know have a high level of social consciousness and responsiveness, had let these traits influence their book more. It was difficult to identify the subject matter as concerning human behavior. We have the opportunity, and I believe the responsibility, to integrate the ever increasing understanding of human behavior into presentations of economic literature. For a comprehensive text, it seemed to overemphasize micro production theory relative to macro theory, consumption theory and institutional problems.

Overall, the book is an excellent synthesis of what is known about agricultural economics. Its contents resemble an outline for a graduate program of study. Economics is so concerned with human problems that such a comprehensive text probably should be more "people-oriented." But that is not a criticism of this book alone. Rather, it merely reflects that social scientists for some time have so busied themselves with developing analytical tools that little energy remains to consider human involvements. This, of course, would have required original work, which the authors disclaimed as an objective.

JOHN SJO
Kansas State University

Heady, Earl O., *A Primer on Food, Agriculture and Public Policy*, New York, Random House, 1967, viii + 177 pp. ($4.95)

A great deal has been written recently concerning the population explosion and the impending food crisis, as well as governmental policy affecting agriculture. This book represents another literary effort to capitalize on subjects that have proven capable of arousing public interest.

The author begins the book with a basic discussion of the role of food in the world's economy and the problems encountered by the agricultural segments in various stages of development. Past governmental policies and programs with respect to agriculture are cursorily reviewed. Policies are classified as to whether they have been developmental or basically compensatory and regulatory in nature. The serious conflict between simultaneous compensatory and developmental policies is emphasized. Reasons for the nation's failure to resolve these conflicts are enumerated.

The author lists goals that he believes should prevail for future agricultural policy. He then outlines policy alternatives to accomplish those goals for two groups of rural residents: those who must leave and those who will stay. The book ends with a discourse on the so-called world food crisis and potential roles of the United States in alleviating the crisis.

The author's stated objective was to write a book for the student and citizen rather than the professional economist. Although a worthy goal, it appears, in this case, to have been a rather elusive one. The student interested in a precise accounting of past legislation affecting agriculture will need to look elsewhere, whereas the untutored citizen will certainly have trouble grasping presentations of rather technical concepts such as price and income elasticity.

It is questionable if Mr. John Q. Citizen will feel inspired to read further after encountering sentences such as the following (p. 149):

> "A long-term program should provide for a gradual shift to more complete reliance on the pricing mechanism in resource allocation and allow diversion of some Treasury outlays to other public services and welfare needs that arise with a larger population, greater per capita income, and increased leisure time."

Students complying with assigned readings may repeat such sentences the number of times necessary to grasp the ideas presented. Laymen are not likely to have the patience.

There is little in the book that is new or unique. However, there are some points with which one might disagree. Subject to question is the somewhat arbitrary selection of a dollar income level below which rural people are automatically branded as poverty stricken folk who *must* move elsewhere. There are many people with annual money income considerably below $5,000 who, by their own standards, have ample food, clothing, and shelter. In at least one mountainous region, many so determined "poverty stricken" families have the financial means of acquiring the mechanical conveniences that they are pitied for not having. They simply have a greater preference for savings. How much beyond adequate nutrition, clothing, and shelter must families have before they can escape this poverty classification?

Many farmers who fit into the author's category of those who by decree must go have not yet been reached by the technical aid the government has in theory been providing rural residents for over half a century. It is possible that the long run welfare of the people as individuals and the nation as a whole would be best served by an effective program that enables unskilled individuals to remain in their native habitats and retain some feeling of usefulness to communities. Such a program would seem infinitely more beneficial than programs that result in further crowding of "surplus human resources" onto the welfare rolls in the ghettos of cities to which displaced unskilled rural residents migrate. Government retraining schools teaching skills of hair dressing and tractor driving have not as yet materially altered this course.

Although the author states that a gradual shift to more complete reliance on the pricing mechanism in resource allocation offers the best hope for the future, his policies for those who remain on farms manifest little faith in this technique as a means of attaining production adjustment. At a time when the effective demand for agricultural commodities in developing countries is increasing, it is discouraging to see domestic producers withdraw further from these markets by seeking higher support prices for their products in order to get a "fair return." The government, at the same time, must offer more lucrative payments to farmers to induce acreage retirement to defer the tremendously profitable agricultural production that such "fair prices" generate.

The suggestion, in view of the "impending world food crisis," of opening the gates and allowing American farmers to produce to capacity at current domestic price levels is frightening. It makes as much sense as asking residents in a flooded area of the Mississippi Valley to increase the water supply by operating their pumps because there are areas in West Texas that are suffering from severe drought.

There are areas today where any gain in food supply is quickly consumed by increased population growth. By extrapolating such growth rates, some people are quickly led to the conclusion, just as Malthus was, that humanity faces world wide starvation within a calculated period of time. Overlooked is the simple fact that population cannot grow at such astronomical rates unless additional food is first provided. It seems folly to worry about food crisis the author predicts in three decades when it is basically starvation *now* that is keeping population growth in check in high growth potential countries, just as it has throughout most of recorded history.

Perhaps the author's concern for starving humanity is not as misdated as his predictions would indicate. In the closing passages of the book, he places a severe indictment on all people of financial means when he states (p. 162):

> "Murdering well-fed people is really no worse than allowing masses of people to suffer and perhaps die from insufficient food and health facilities."

Most of us have some capacity for preventing this kind of suffering and death.

GENE D. SULLIVAN
Louisiana State University

McPherson, W. W., ed., *Economic Development of Tropical Agriculture—Theory, Policy, Strategy and Organization*, Gainesville, University of Florida Press, 1968, xvi + 328 pp. ($8.50)

The reviewer of a collection of essays faces an enormously difficult task because the frontage covered is usually broad and the merit of the individual essays cannot be adequately evaluated or even summarized in a sentence or short paragraph. This collection is no exception! It consists of fifteen essays by eleven authors, inclusive of the editor's introduction.

The implicit purpose of most collections is (a) to assemble scattered works bearing on some issue or set of issues not adequately covered by an existing monograph, or (b) to fill voids in the literature by inviting original contributions on a specifically identified subject. Both are needed. But the purpose of this volume is by no means clear. Examination of the content suggests that the title's clues to the organizational scheme are more an *ex poste* classification of the contents than an attempt to fulfill one of the above objectives by systematic selection of contributors and topics. To this reviewer, they do not comprise a very coherent whole. The term "tropical" in the title could be as aptly applied to almost any of the standard works on economic development, the general idea content of this book being, without obvious exception, as relevant to Tibet as to Tanzania, or to Korea as to the Congo. The fact that a majority of the empirical materials are taken from tropical areas is irrelevant, because the developmental problems peculiar to agriculture in tropical areas are scarcely mentioned, much less analyzed.

The above comments are meant to imply neither that the individual contributions are valueless nor that all of the contributions are unrelated. On the contrary, five of the essays, involving about 120 pages, would have made a useful small symposium on agricultural developmental planning and organization, especially if a brief introduction and summary had been added. Two essays by Arthur Gaitskill draw insightfully upon his vast experience and knowledge of the historical background in subSahara Africa and India, and Pakistan (Indus Basin), and two by James W. Green are on the closely related areas of development organization and advising on development organization. These, plus a general treatment by J. Price Gittinger of "Planning Characteristics of Low-Income Agriculture," provide useful perspectives on the interrelationships that must be taken into account when the specialist is sorting out relevant issues and analytical approaches in his own field. However, despite the coherency suggested by the "Theory, Policy, Strategy . . ." terms in the title, the remainder of the collection is best described as miscellany, albeit high quality miscellany in some instances.

Evidence to the above point is found in the character of two essays immediately following the editor's introduction. The "Theory" component of the book is supplied by John C. H. Fei and Alpha Chiang in a pure theory paper on "The Fundamental Cause of Economic Stagnation," which is supplemented by a five-page mathematical appendix. Its stated purpose is to explore the proposition that "when static technology subject to the law of diminishing returns is coupled with persistent population pressure (constant rates of increase), economic stagnation is bound to result." It has no special connection with agriculture, except by way of a cursory reference to Ricardian rent theory, and no conceptual connective tissue is built between this proposition and any of the other essays. This is followed by a largely common-sense level review of "The Importance of Agriculture in Economic Development," by Arthur Gaitskill, mainly restating the points covered in earlier works by such people as W. D. Nicholls [4] and Mellor and Johnston [3].

Earl O. Heady's paper mainly restates his rather "comfortable" position. He says (p. 59), "The knowledge is already at hand, theoretically and practically, in explaining the economic development of agriculture." To students of agricultural development, this is familiar doctrine. It serves in this book mainly to sharpen the implications of the orthodox methodological point-of-view, as it applies to agricultural development, and to contrast them with the implications of the point-of-view implicit in the papers on planning and explicit in the paper by Richard King on product markets. This latter point-of-view would seem to be based on (a) the assumed unity of problems as investigational units and (b) the corollary research objectives of the identification and evaluation of available alternatives in the situation. In this context, King suggests that the perfect market concept is perhaps one of our most useful conceptual tools.

Glenn Johnson's paper follows and distinguishes between structure and operation of factor markets, respectively, on the basis of (a) public policy and institutions and (b) (implicitly) everything else that marketing researchers study, including competitive structure. He mainly observes, without firm performance tests or even explicit criteria, that factor markets in Nigeria work quite well, but that in many respects policies of taxation, export levies, and the like, have adversely affected incentives for productivity-increasing innovations and resource allocations. He provides interesting glimpses of several policy problems. But in trying to cover the entire frontage of land, credit, purchased input and labor markets, nothing was (or could be) treated rigorously.

The remainder of the book consists of a recasting and condensation of Vernon Ruttan's (and S. C. Hsieh's) useful Stanford Food Research Institute paper [2] on "Environmental, Technological and Institutional Factors in the Growth of Rice Production . . ." (data on Taiwan removed), a paper on dynamic linear programming applications to less-developed areas by Max Langham, the concluding paper by Arthur Coutu on the role of United States universities abroad, and a paper on "Trade Preferences and Developing Countries" by Harry G. Johnson, formerly published in *Lloyds Bank Review*. The last is probably the most useful single article in the collection, because it touches on an area relatively little studied and in which agricultural economists are typically a bit short of training.

This collection will provide some worthwhile reference material for inclusion in institutional libraries. While, on balance, it can hardly be regarded as a substitute for the earlier collections prepared by Eicher and Witt [1] and by Southworth and Johnston [5] with their more coherent organization and more pointed definition of issues, several of the papers will be distinctly useful in courses on agricultural development.

Schickele, Rainer, *Agrarian Revolution and Economic Progress: A Primer for Development*, New York, Frederick A. Praeger, Inc., 1968, xix + 410 pp. ($15.00)

"Development" is popular these days and it is inevitable that, amidst a literature that is burgeoning, a good deal of recapitulating will take place, some of it not overly productive. This title is a case in point.

It is the second book published by Praeger for the Agricultural Development Council, Inc. The first was *Getting Agriculture Moving: Essentials for Development and Modernization*, a popularization intended to persuade decision-makers in low-income countries to pay more attention to agriculture. Modesty was the keynote. Nothing new, the Preface confessed, is contained in this book. "Only the organization of the materials, and a few of the implications for agricultural development drawn from widely known facts and ideas, are original contributions of the author."

Apparently a need was felt for Mr. Schickele to carry the art of organizing and implying to its logical next stage; the essentials mastered, our decision-makers are now ready for a good, solid primer. This is all the more unfortunate because Mr. Schickele is a man of no small international experience, having among other things, served for twelve years as head of FAO's Land and Water Development Division and more recently in Peradeniya as an Agricultural Development Council Visiting Professor. Without a doubt he has much to contribute, but instead he finds himself in a position where he is obliged to try to say all superficially.

Mr. Schickele writes well and he knows that if he's going to get his message across he had better get us interested right at the beginning. And what better way to do this than by starting off with a discussion of the world food problem. "Produce or perish," he advises. We are interested, but not terribly enlightened.

There follow two chapters which are useful. Mr. Schickele has a conscience, a welfare economist in the proper sense, and he reminds us of the limitations of the market place as a guide for decision making and of the limitations of the conventional criteria for gauging economic progress. Nothing new, to be sure, but it warrants re-emphasizing from time to time.

The respite is brief. In the remainder (and bulk) of the book, Mr. Schickele attempts to strike a positive note and, by summarizing the collected wisdom on hastening rural development, to suggest that the world agricultural outlook is far from grim. The result is disappointing. The common denominators that emerge from the distilling process are so common as to come dangerously near to insulting the reader's intelligence. A Minister of Finance, with money to spend? No problem, Excellency. Simply turn to Chapter 7 and hear of schools, roads, and marketing facilities. A dull and listless peasantry? Relax. Land reform is clearly in order. Chapter 8 contains several prescriptions. Or perhaps your problem is wide open spaces, crying for the plowman. That's a tougher one, says Chapter 9, but if the Gezira succeeded, so can you.

And so it goes—not quite, of course, but just about—for over 400 pages.

The great majority of decision-makers abroad are neither dull nor uninformed. Like the people they serve, they are keen, in a hurry, and, above all, aware of their limitations. Advice and guidance they seek, but more than the threadbare maxims of twenty years ago—especially at fifteen dollars a copy.

SUPPLEMENTARY NOTE ON CONTRIBUTED PAPERS 1969 AAEA ANNUAL MEETING

Plans for presenting contributed papers are being modified this year. As in previous years, several sectional meetings are planned where selected contributed papers will be presented. But it is not intended that the presentation of contributed papers will be limited to special sessions. Where a paper fits into the topic of another planned session, it may be included along wth regularly invited papers. This applies to papers that have been submitted *before May 1, 1969.*

AAEA EMPLOYMENT SERVICE

The AAEA Employment Committee will provide services to assist the following groups during the annual meeting on August 17–20, 1969, at the University of Kentucky:

a. Employers seeking staff
b. Individuals seeking employment

Two separate forms for job applications will be used. One is oriented toward the needs of students completing their graduate programs. The second form is designed primarily for professionals in government, academic, and business positions and will be identified by code number. This latter form is briefer and lends itself toward more anonymity than does the former.

The appropriate forms as well as additional information will be sent to all AAEA members in June and also to a number of academic, government, and business employers who may choose to use the service.

Individuals or organizations who are not members of the AAEA may obtain forms from:

LOYS L. MATHER
AAEA Employment Committee
Department of Agricultural Economics
University of Kentucky
Lexington, Kentucky 40506

ANNUAL MEETING
WESTERN AGRICULTURAL ECONOMICS ASSOCIATION

The 1969 annual meeting of the Western Agricultural Economics Association will be held at Oregon State University, Corvallis, July 20–23.

Russell Youmans, chairman of local arrangements, is sending WAEA members detailed information about the meeting.

Following is a brief summary of the program:

SUNDAY, JULY 20

Afternoon Council meeting
Evening Reception

MONDAY, JULY 21

Forenoon "Western Agricultural Economics in the 1970's"
Questions of relevance and future directions of our teaching, extension and research programs; our relationships with industry; and the WAEA.

Afternoon Contributed Papers Sections
Titles and abstracts of papers to be considered should be sent to the sectional chairmen listed below by June 1:

Commercial Agriculture

Dr. E. R. Barmettler
Division of Agricultural Economics & Education
University of Nevada
Reno, Nevada 89507

Natural Resource Development

Dr. Norman E. Landgren
Department of Economics
Colorado State University
Fort Collins, Colorado 80521

Community and Human Resource Development

Dr. James C. Barron
Department of Agricultural Economics
Washington State University
Pullman, Washington 99163

Evening Salmon bake

TUESDAY, JULY 22

Forenoon "Agricultural Policy"

The latest from Washington, D.C.; social and political dilemma of the agricultural sector and agricultural institutions; the consumers' role in the agricultural coalition.

Annual business meeting

Noon WAEA Luncheon

Presentation of awards; installation of 1969–70 officers; brief speech of general interest.

Afternoon "International Development and Trade"

Developments in agricultural production in high-change countries; interactions among food supply, population, technology and development; developments in international trade.

"Regional Analysis and Economic Development"

Problems and opportunities in domestic economic development; rural and urban poverty; reports on regional and area development research; report on work in marine economics; report on extension program in community resource development.

WEDNESDAY, JULY 23

One or more educational tours arranged by the Oregon State University staff.

INTERNATIONAL ASSOCIATION OF AGRICULTURAL ECONOMISTS 1970 CONFERENCE: CONTRIBUTED PAPERS

Papers on topics in any field of agricultural economics will be accepted; however, papers on (1) "Risks and Uncertainties: How to Take Them into Account in Farm Planning" and (2) "The Econometric Study of Supply Determinants" are especially invited.

In choosing papers for presentation at the Conference, the selection committee will give preference to those having the following characteristics:

1. Papers having relevance in a world context.
2. Papers presenting new and original approaches to problems rather than reviews of the existing literature.
3. Papers likely to provoke or stimulate discussion at an international conference session.
4. Papers on topics not covered at other sessions of the Conference. (Details of the draft program may be secured from country correspondents.)

Papers must be in the hands of the Chairman of the Committee,

Professor K. O. Campbell
Department of Agricultural Economics
University of Sydney
Sydney, N.S.W. 2006
Australia

not later than January 15, 1970. (The Conference meets August 24 to September 2, 1970.)

Papers should be in English and not exceed 3,000 words (including text, footnotes, tables, and charts). Manuscripts should be typewritten (black ribbon), single-spaced, using one side of plain white paper. Recent issues of the *Proceedings* of the Association should be used as a guide.

(The above is briefed from the announcement of the Executive Committee. Further inquiries or requests for the complete announcement should be addressed to Professor Campbell or to country correspondents. U. S. members may contact Joseph Ackerman, Farm Foundation, 600 South Michigan Avenue, Chicago, Illinois 60605, or K. L. Robinson at Cornell.)

NEW DEAL AGRICULTURE BIBLIOGRAPHY

The Agricultural History Branch of the U.S. Department of Agriculture and the Agricultural History Center at the Davis Campus of the University of California are cooperating to compile, in sections, a comprehensive bibliography of American agricultural history. Recently published is "A Preliminary List of References for the History of American Agriculture During the New Deal Period, 1932–1940," compiled by Harry C. McDean. The list is available upon request to the Agricultural History Center, University of California, Davis, California 95616. Other bibliographies also available on request are those for California, the Granger Movement, and the Pacific Northwest and Alaska.

AAEA DUES

Dues for 1969 are payable. The dues rates are as follows:

Regular membership	$10.00
Junior membership (graduate students, 3-year maximum)	5.00

Please mail your check, payable to the American Agricultural Economics Association or AAEA, to C. D. Kearl, Secretary-Treasurer, AAEA, Department of Agricultural Economics, Cornell University, Ithaca, New York 14850.

WESTERN AGRICULTURAL ECONOMICS ASSOCIATION

The annual dues rates are as follows:

Regular membership	$3.50
Student membership (with student status certified by department)	1.00

Mail application and check to Leo R. Gray, Secretary-Treasurer, WAEA, Post Office Box 89, Berkeley, California 94701

SOUTHERN AGRICULTURAL ECONOMICS ASSOCIATION

Annual membership dues (includes proceedings issue of SJAE)	$3.00

Direct correspondence concerning membership to John C. Redman, Secretary-Treasurer, SAEA, Department of Agricultural Economics, University of Kentucky, Lexington, Kentucky 40506.

CANADIAN AGRICULTURAL ECONOMICS SOCIETY

Annual membership fees	(Can.) $10.00

Mail fees to Treasurer, CAES, Box 632, Postal Station B, Ottawa, Ontario, Canada.

News Notes

AGRICULTURAL DEVELOPMENT COUNCIL

APPOINTMENTS: **William L. Collier**, Ph.D. Hawaii, Agricultural Economic Survey, Indonesia Ministry of Agriculture, Bogor, Indonesia; **Donald C. Taylor**, formerly of American University of Beirut, visiting professor (2 years), Mysore University of Agriculture Sciences, Bangalore, India.

ECONOMIC RESEARCH SERVICE, USDA

(EDD is Economic Development Division; ESAD is Economic and Statistical Analysis Division; FDTD is Foreign Development and Trade Division; FPED is Farm Production Economics Division; FRAD is Foreign Regional Analysis Division; MED is Marketing Economics Division.)

APPOINTMENTS: **Patrick P. Boles**, MED at Columbus; **Charles P. Butler**, FPED at Clemson, as coordinator of newly formed Regional Technical Committee for Cooperative Regional Research Project S-67; **Raymond Christensen**, Director (formerly Deputy Director), FDTD; **Edward V. Jesse**, MED at Madison; **William T. Manley**, Acting Director (formerly Deputy Director), MED; **Levi A. Powell, Sr.**, Assistant to Director, MED; **Roger Wilsie**, Portland, Oregon.

TRANSFERS: Robert W. Bohall, MED, from North Carolina State University to Washington, D.C.; **Rex F. Daly**, from Chairman, Outlook and Situation Board, to Director, ESAD; **Lawrence Davidoff**, from FDTD to Assistant Agricultural Attache, FAS, Bonn, West Germany; **Kenneth R. Farrell**, from Director, MED, to Acting Assistant Administrator, ERS, and Chairman, Outlook and Situation Board; **Warren R. Grant**, FPED, from College Station, Texas, to Davis, California; **Ronald E. Kampe**, from FRAD to EDD as Assistant Chief, Area Analysis Branch; **J. B. Penn**, FPED, from Baton Rouge, Louisiana, to Lafayette, Indiana; **W. Neill Schaller**, from FPED to International Agricultural Development Service.

LEAVE: **Stanley S. Johnson**, FPED, returned from 2-year assignment with Rice Research Institute, Philippine Islands.

RESIGNATIONS: **Arthur F. Bordeaux, Jr.**, MED, to University of Kentucky; **Anne E. Hammill**, NRED, to economist with Federal Reserve Board, Washington, D.C.

RETIREMENTS: **Edgar B. Hurd**, FPED, after 39 years of Federal service; **John H. (Dixie) Southern**, Director, EDD, after 33 years of Federal service, to head Ford Foundation program in Nepal.

IOWA STATE UNIVERSITY

APPOINTMENTS: **Walter W. Haessel, Gerald A. Harrison,** and **Arthur I. Stoecker,** research associates, Department of Economics.

UNIVERSITY OF MANITOBA

APPOINTMENT: **Norman J. Beaton,** Ph.D. Kansas State, assistant professor.

LEAVE: **Sol. Sinclair,** returned as professor and appointed Director, Natural Resources Institute, after 2 years as Head, Development Planning Division, Kenya Ministry of Agriculture.

UNIVERSITY OF NEBRASKA

APPOINTMENTS: **Douglas Genereux,** M.S. Nebraska, assistant to Campus Coordinator of International Programs; **Allen C. Wellman,** assistant professor.

LEAVE: **Loyd K. Fischer,** returned as professor after 2 years in Bogota, Colombia.

UNIVERSITY OF NEW HAMPSHIRE

APPOINTMENTS: **Edmund Jansen,** formerly with University of North Carolina, and **Sherrill B. Nott,** Ph.D. Cornell, to faculty in resource economics.

NORTH CAROLINA STATE UNIVERSITY

APPOINTMENTS: **Jimmie Bruce Bullock** and **Gerald A. Carlson,** assistant professors.

LEAVE: **Richard A. King,** University of California, Berkeley (6 months).

TEXAS A&M UNIVERSITY

LEAVE: **Charles Baker,** rejoined staff after 2 years in Dominican Republic.

RETIREMENT: **Clifton H. Bates,** as farm management specialist since 1946.

UNIVERSITY OF WISCONSIN

APPOINTMENT: **Richard Hilliker,** Ph.D. Wisconsin, assistant professor.

LEAVE: **Bernard Erven,** returned as professor after 2-year assignment with Wisconsin-AID program, University of Rio Grande do Sul, Porto Alegre, Brazil.

OTHER APPOINTMENTS

Galen Blomster, Ph.D. Purdue, National Cash Register Company, Dayton, Ohio.
Lon C. Cesal, Purdue-AID project at Rural University, Minas Gerais, Brazil.
Jeane Chen, M.S. Nebraska, State Labor Department, Lincoln, Nebraska.
Robert Leon Coppersmith, visiting lecturer, University of Missouri.
Eduardo de la Espriella, Esso Standard Oil Company, Costa Rica.
Geoffrey Ferster, Ph.D. Cornell, staff, University Dar Es Salam, Tanzania.
Melvin From, M.S. Nebraska, Omaha National Bank, Omaha.
Yaaqov Goldschmidt, Ph.D. Cornell, economist, Inter Kibbutz Economic Advisory Unit, and faculty, Graduate School of Business Administration, Tel Aviv University.
Bengt S. Gustafsson, Ph.D. Purdue, research leader in agricultural economics, Farm Structures Research Institute, Lund, Sweden.

John Holmes, M.S. Nebraska, Ralston Purina Company, Newberg, Oregon.

John Hyslop, M.S. Missouri, manager of farm operation, Bennett Wholesale, Inc. Bloomfield, Missouri.

H. Bruce Huff, Ph.D. Michigan State, assistant professor, University of Guelph.

Kazumi Kobayashi, Ph.D. Cornell, faculty, Kyoto Szngyo University.

M. L. Lerohl, editor, Canadian Journal of Agricultural Economics.

Patrick Lubischer, M.S. Nebraska, Pathfinder Company, Fremont, Nebraska.

James C. Martin, Ph.D. Missouri, associate professor, Murray State University, Murray, Kentucky.

Gordon A. MacEachern, formerly of Purdue, President, Agricultural Economics Research Council of Canada.

Marcelo Peinado, Ph.D. Wisconsin, assistant professor, Utah State.

Al Reiners, M.S. Nebraska, Bureau of Reclamation, Boise, Idaho.

L. S. Venkataramanan, formerly visiting professor, Minnesota, Head, Division of Agricultural Economics, Indian Agricultural Research Institute, Pusa, India.

Moshe Weiss, Ph.D. Cornell, research section, Sun Oil Company, Philadelphia.

James G. Yoho, formerly of Duke University, Head, Department of Forestry, Mississippi State University.

AWARD

Clifton B. Cox, group vice president, Armour Foods, and a director, Armour & Company, honorary Doctor of Science degree, Auburn University.

OBITUARIES

Bushrod W. Allin, chairman of USDA's Outlook and Situation Board for nearly 20 years, died November 18 of pneumonia in Washington, D.C. Dr. Allin had retired in 1965, after receiving the USDA Distinguished Service Award—the Department's highest distinction—for his outstanding leadership in developing and coordinating the USDA agricultural outlook services as a practical aid to farmers and agribusinessmen. He was president of the American Farm Economics Association in 1962 and was elected a Fellow of the Association in 1965.

Dr. Allin was noted as a skillful writer and effective speaker, as well as a leading economist. He co-authored several books, as well as articles for the *Journal of Farm Economics,* the *Encyclopaedia Britannica,* and numerous bulletins, speeches and reports.

He was born on a farm near Harrodsburg, Kentucky, on August 28, 1899. He grew up in Texas, served in the Army during World War I, and was graduated from the University of Wisconsin in 1921 with a B.S. in agriculture.

Dr. Allin worked two years for USDA as a farm cost accountant before returning to Wisconsin, where he earned his Ph.D. in 1928. After that, he returned to the USDA and advanced rapidly through the ranks of economists in the Bureau of Agricultural Economics. He headed the Bureau's Division of State and Local Planning from 1938 to 1942.

Walter Henry Pierce, Professor Emeritus of Economics at North Carolina State University, died on November 9, 1968, in Raleigh, North Carolina, at the age of 52. He had retired on April 1 with over 22 years of service with the Department of Economics.

Dr. Pierce received the B.S. degree in agricultural economics from N.C. State in 1936 and his M.S. in 1948 and his Ph.D. in 1953 from the University of Minnesota. He was employed as assistant farm management specialist with the North Carolina Agricultural Extension Service until October, 1938. He transferred to the USDA (BAE), Division of State and Local Planning until May 21, 1941, when he was called to active duty in connection with World War II. Since his release from active duty in 1945 as a Lt. Colonel, Dr. Pierce had been involved in teaching and research in various fields of agricultural economics at North Carolina State University. He authored or co-authored more than 75 publications during his career.

DOCTORAL DEGREES CONFERRED IN AGRICULTURAL ECONOMICS, 1968

Mani Ali Afifi, B.S. Ain Shams University, 1960; M.S. University of California, 1964; Ph.D. University of Hawaii, *An Econometric Study of the Competitive Position of Hawaii Broiler Industry.*

ECONOMICS OF AGRICULTURAL PRODUCTION, MARKETS, and POLICY

By JOHN P. DOLL, V. JAMES RHODES,
and JERRY G. WEST,
all of *University of Missouri*

Here is the newest, most thorough and intelligible book yet published in the study of agricultural economics. Designed as a basic text, it has supplementary value for courses in agricultural marketing or agricultural policy. Each of the text's three topics—production, markets, and policy—is discussed at length in three separate sections while a unifying theme of economic theory is developed and enlarged throughout.

- **PRODUCTION . . . is devoted to the economics of production on farms, presenting mainly from theory, those topics of particular importance to agricultural production reseach.**
- **MARKETS . . . contains discussion of the structure of markets, the nature of competition among farmers, marketing firms, and food retailers.**
- **POLICY . . . develops the historical and present-day role of government in the agricultural economy and makes application of the theory developed in earlier chapters to government policies.**

570 Pages, Text Price $9.25

READINGS IN THE ECONOMICS OF AGRICULTURE

Edited by Karl A. Fox, *Iowa State University*,
and D. Gale Johnson, *University* of *Chicago*

This collection provides useful information to graduate students and professional economists who wish to have a general overview of the major analytical problems tackled and methods used by leading agricultural economists in the period subsequent to World War II. This is one of a series of volumes of readings in various fields of economics sponsored by the American Economic Association.

Agricultural Marketing Economists

are sought by the Food and Agriculture Organization of the United Nations for present and projected posts in developing countries.

IF YOU HAVE:

—appropriate university degree;

—at least five years of research and/or practical experience in agricultural marketing economics;

—good working knowledge of English, French or Spanish.

WE CAN OFFER:

—competitive tax-free salaries, based on depth and breadth of training and experience;

—other liberal benefits.

Interested candidates should send full résumé to the Chief, Recruitment Section, FAO, Viale delle Terme di Caracalla, 00100 Rome, Italy, quoting Ref. GP/Markg/JFE. Formal application forms will be sent to suitably qualified candidates.

"If men are, as Leo Tolstoy eloquently phrased it, 'blown by the winds of history,' then Henry A. Wallace was destined to occupy a major role in farm politics. Conscience was his master and agriculture his cause. Whether right or wrong, wise or unwise, Wallace's life was one of courageous consistency."

HENRY A. WALLACE OF IOWA:

The Agrarian Years, 1910-1940

Edward L. and Frederick H. Schapsmeier

Although well recognized as a major personality and influence in the New Deal era, Henry A. Wallace has up to now been neglected by the historians of that period. The Schapsmeiers have filled that gap with their thorough examination of the origins and development of the Wallace political philosophy.

By tracing and analyzing Wallace's evolving thought in the context of contemporary events, they depict his genius in his varied roles of scientist, economist, farm editor, and original thinker in agricultural policy. Special emphasis is placed on his relationship with Franklin D. Roosevelt and his contributions to the Roosevelt administration as Secretary of Agriculture, administrator of the vast farm programs, spokesman for rural America, and philosopher for the New Deal programs.

While the main focus of the book is on Henry A. Wallace, the authors also cast light on several other areas. They reveal the importance of Henry C. Wallace as a Progressive leader in the era of Harding and Coolidge; present new insights into the importance of the McNary-Haugen movement in the formulation of agricultural policy for the agrarian sector; and evaluate the influence of Populism and Progressivism in the New Deal farm coalition. In addition, they assess the role of agricultural economists as architects of specific farm legislation.

Historians will find this a comprehensive, significant, and worthwhile study of one of the great figures in American agricultural history.

The JOURNAL OF BUSINESS is published quarterly by the University of Chicago Press. Subscriptions are $8.00 per year (individual) and $12.00 per year (institutional) and should be addressed to the University of Chicago Press, 5750 South Ellis Avenue, Chicago, Illinois 60637. Manuscripts in duplicate, typed and double-spaced (including footnotes and quotations), and editorial correspondence should be addressed to Irving Schweiger, Editor, JOURNAL OF BUSINESS, Graduate School of Business, Haskell Hall, University of Chicago, Chicago, Illinois 60637.

From The Macmillan Company

Modern Breeds of Livestock, Third Edition

By Hilton M. Briggs, South Dakota State University

This classic text has been revised to reflect current developments and research, and includes material on new and developing breeds, with particular emphasis on the shifting population of various breeds of livestock. Organized on the basis of an historical presentation and evaluation of each breed, the book is designed to acquaint the student with the special attributes and limitations which determine the past importance and future potential of the breeds of livestock generally found in the United States. Charts, tables, and illustrations have been extensively updated.
1969, approx. 752 pages, $12.95

Marketing of Agricultural Products, Third Edition

By Richard L. Kohls, Purdue University

Widely adopted in its previous editions, this basic textbook has been completely updated to keep pace with changes in the organization and functioning of the nation's food marketing system. Changes in the third edition include increased emphasis on market organization and the concept of multiple markets for farm products.
1967, 462 pages, $9.95

Farm Business Management: The Decision-Making Process

By Emery N. Castle and Manning H. Becker,
both of Oregon State University

This study of farm business management presents practical functions and problems of the manager with emphasis on the farm record as an analytical tool. Other topics include economic principles, the matter of risks and uncertainty, and off-farm considerations.
1962, 423 pages, $7.95

Write to the Faculty Service Desk for examination copies.

EDITORIAL COMMUNICATIONS

Editorial communications, including manuscripts submitted for publication or inquiries concerning the JOURNAL, should be addressed to Varden Fuller, Department of Agricultural Economics, University of California, Berkeley, California 94720. (See inside back cover for Guide for Submitting Manuscripts.)

Communications concerning books for review and books submitted for announcement in the JOURNAL should be addressed to Allen B. Paul, Economic Research Service, United States Department of Agriculture, Washington, D.C. 20250.

SUBSCRIPTIONS

- Members of the American Agricultural Economics Association receive the JOURNAL as part of their membership.
- Yearly subscriptions, $10. Price this issue $2.50.
- Subscriptions, orders for individual copies of the JOURNAL and changes of address of subscribers should be addressed to C. Del Mar Kearl, Department of Agricultural Economics, Cornell University, Ithaca, New York 14850.

- The AMERICAN JOURNAL OF AGRICULTURAL ECONOMICS is issued five times a year, in February, May, August, November, and December. Prior to 1968, this JOURNAL was the JOURNAL OF FARM ECONOMICS.
- Published by the American Agricultural Economics Association.
- Printed by the George Banta Company, Inc., Menasha, Wisconsin, U.S.A.
- Second-class postage paid at Menasha, Wisconsin.

Shifts in Entrepreneurial Functions in Agriculture*

MARSHALL HARRIS

Substantial elements of entrepreneurship in agriculture are being shifted to off-farm firms and government agencies. These shifts involve public programs that control land use and guide its development and that take private land for public purpose. In the private sector, they include substitution of corporate enterprise for family farming, restrictions on freedom of action under credit arrangements, control over tenant-operated farms, direction of management under vertical coordination contracts, and control of farmer cooperatives and bargaining associations over buying and selling. In the future, family farming may be under pressure to meet technological requirements, and corporation farming may offer competition. In the absence of a massive support program, the family farmer may continue to shift elements of entrepreneurship to off-farm firms. An important question is: What is happening to farmer entrepreneurship under the impact of modern technology and urbanization?

MANY farm operators are transferring important elements of entrepreneurship to off-farm businesses and governmental agencies. Such entrepreneurial shifts are a part of the structural revolution in today's agriculture. They frequently are so subtle that they are overlooked among more obvious technological innovations. Separation of ownership, management, and labor is taking place at an increasing tempo. Concurrent technological and structural revolutions perhaps will become known as the "Agricultural Revolution of the 20th Century." It may parallel the earlier Industrial Revolution in the nature and magnitude of changes in the organization and operation of production processes.

Shifts in entrepreneurial functions seem to be of such magnitude that resultant changes in the organizational structure of the farming industry need review. What is happening to entrepreneurship in farming? Some ideas about the magnitude of changes that are taking place are presented without any attempt to measure them precisely. The first task is one of gaining some insight into the nature of the shift of entrepreneurial functions.

The prime objective of this article is to illustrate an analytical framework within which the evolving structural organization of agriculture may be researched and understood more fully. Other objectives are to show (1) the relationship between the technological revolution and selected institutional arrangements in agriculture and (2) significant shifts in entre-

preneurship to off-farm firms (without trying to delineate means of measuring their magnitude), and to raise some questions that typify the kinds of research needed in the short run.

Background

Since its beginning, the nation has tried to create an environment in which many forms of farm organization would thrive. It has also tried to create an economy (with laissez-faire and free-enterprise as hallmarks) in which each farmer would have maximum freedom of choice consistent with maintenance of property rights and domestic tranquility. As a consequence, family farms, plantations, ranches, and part-time and part-retirement farms have thrived side by side.

The granting of land to settlers was still in process when family farms apparently needed special support and treatment. The U.S. Department of Agriculture, state agricultural experiment stations and extension services, vocational agricultural high schools, and special farm credit institutions were established to serve the needs of the numerous family-farm businesses. Unique privileges were granted farmer cooperatives to help put family farmers in a position to bargain effectively with growing corporate enterprise. Later, a varied group of programs was developed, ostensibly to bolster the integrity of family farming.

Signs of internal adjustments in the family-farm structure began to appear before family farms reached their maximum number. The unencumbered ownership objective of family farming became untenable with increasing land values and subdividing farm property caused by equal devolution. Mortgaged indebtedness and farm tenancy moved in at a rapid rate, especially in rich land areas of high capital requirements per farm. More recent adjustments in conditions under which farms are operated have been made by vertical coordination contracts, farming corporations, and government programs.

The present Agricultural Revolution is composed of two distinguishing characteristics: obvious technological changes, which make the headlines almost daily, and less-proclaimed structural changes, which are obscured in contractual provisions and unwritten rules of the game. Both the technological and the structural phases of the revolution are folowing patterns not unlike those of the Industrial Revolution. Questions that need to be answered include: What are the nature and consequences of current structural changes? Are they becoming so firmly established that meaningful adjustments will be difficult to effectuate in the future? How is the silent structural revolution affecting the farmer's control and management of his business? To what extent are entrepreneurial functions being shifted to off-farm firms? What is happening to the farmer as an entrepreneur?

Independent Farmer

Suppose we gauge entrepreneurship by the departure of current condition from some definable norm. Let us call this norm "independent farmer" and let him be a benchmark or polar extreme. This independent farmer holds fee simple ownership of all the farm real estate that he operates; his ownership is neither subject to reservations nor to encumbrance, such as easements, mortgage, rural zoning, or land-use regulations; he owns all of the capital resources (personal property) that he uses, also unencumbered; he furnishes all the labor (including family labor) necessary to operate his farm; he holds complete managerial control over his entire farming operation; he makes all organizational and operational decisions; his farm business is large enough to yield in a normal year all income needed by his family; and he bears all of the risks and losses and reaps all of the gains of the entire farm business.

Our independent farmer holds the most complete entrepreneurship conceivable. He holds all possible entrepreneurial functions regardless of the time, place, or type situation under observation. Although this concept is set up as a benchmark against which the present entrepreneurial situation in farming may be measured, researched, and evaluated, it is not suggested as a policy goal. It is designed to describe the maximum entrepreneurship that a farmer can hold, so that all departures may be measured as a diminution in entrepreneurship. Although the independent farmer is hypothetical, there are farmers today who approximate it, except for societal reservations.

An independent farmer coordinates his production with off-farm firms through open factor and product markets. The open market has many sellers of inputs and buyers of outputs. Both buyers and sellers are informed adequately of the market situation and both are free to buy and to sell. Any diminution in the open-market specifications would represent a departure from the freely competitive market-oriented economy upon which the efficacy of the independent-farmer benchmark heavily depends.

Entrepreneurship

Entrepreneurship consists of decisions and the association of consequences of these decisions. Entrepreneurship is management, with results of management directly linked to the manager. Entrepreneurs have an interest (a property) in the resources which they manage. Unlike a paid manager, the entrepreneur's return is a function not only of his decision making per se, but of his property interests. He thus manages property and production processes.

Through our conventional imputational procedures, we have some (even if weak) insights into the returns to property. We are far less certain about return to management of production. (Is management a factor of production?) We may sense that the attribute of correct choice making is valuable. We also sense that a wide range of choices makes fullest use of "a maker of correct decisions." The attribute of entrepreneurship is enhanced by a wider range of choice. Because entrepreneurial environments change over time, entrepreneurship can be viewed most usefully in terms of the proportion of all possible choices that are open to the entrepreneur. To this writer's knowledge, these entrepreneurial attributes have not yet been adequately quantified. A difficulty in evaluating a shift in entrepreneurship is measurement of a set of abstract yet definite rights that are bargained against a set of indefinite expectations [4, p. 277].

Entrepreneurship is evidenced by the farmer's rights and responsibilities, benefits and burdens, and rewards and risks in the business that he operates. Any subtraction from rights, benefits, or rewards represents a diminution in entrepreneurship, as defined here. Any addition to responsibilities, burdens, or risks correspondingly means a weakening of the entrepreneur's position.

Entrepreneurship can be analyzed largely in terms of the independent farmer, as defined. It can be assayed from several viewpoints: How does the entrepreneur gain access to resources? Who performs entrepreneurial functions? Who holds control? Who acts in decision making? How does the entrepreneur behave? What is happening to his claim on economic returns?

The quantity of entrepreneurship held by an independent farmer is the total of all entrepreneurial functions at a given time and situation. For example, a farmer who homesteaded a century ago could have held all entrepreneurship, excepts rights reserved by society, in his 160-acre homestead, although the amount of capital invested was negligible and management inputs were small indeed compared with today's requirements. Our concept of entrepreneurship does not presume absolutes. The main concern is with the freedom of the farmer to choose, regardless of the range in choice. The focus is on whether the farmer holds all entrepreneurship or part or all of it has been transferred to or assumed by off-farm entities or reserved under the sovereign power of society.[1]

Societal Reservations

The tendency is almost universal to think of fee simple ownership as full, complete, and absolute. Yet, over the years, society has reserved at least five rights in privately held land: the right to tax, the right to take for public purpose, the right to police, the right of escheat, and the spending power. These well-established societal rights can be used to reduce the rights or values of property and the choices in productive processes available to the farmer.[2]

---

[1] No endeavor is made to present the evidence needed to properly evaluate what is happening. The shifted entrepreneurship may be much less valuable than the gain in economic growth, income, or status. If the shifts in entrepreneurship appear to be in the right direction after adequate study, they may need to be improved and expedited. A central thesis of this paper is that shifts in entrepreneurship should be analyzed and evaluated now, rather than after they become further institutionalized.

As society becomes more complex and integrated, group decisions based on one or more of these societal reservations increasingly set the bounds of individual action. Societal actions that reduce entrepreneurship of the farmer doubtlessly will be of increasing importance in the foreseeable future. Some societal actions, however, have increased the choices available to the farmer, for example, large public investments in agricultural research.

Property taxes may reduce entrepreneurship and do it unequally. A sovereign government need not tax farm real estate—the Federal government does not. Such taxes are becoming less important than formerly in many units of government. Nevertheless, taxes may affect entrepreneurship in the following ways: reduction in ownership through tax foreclosure; encouragement of exploitative use to meet fixed annual tax payments; imposition of unequal burdens because of inequities in assessments and levies, and because of special exemptions, e.g., homestead exemptions; adjustments in inventories to minimize taxes; modification of time of sale of products to meet fixed tax date; selection of relatively stable income enterprises to meet relatively stable (albeit increasing) tax payments; and reduction of capital available for development of resources, accumulation of capital, and family living.

One measure of the shift of this element of entrepreneurship is the amount or proportion of the annual net income taken by taxes. Property taxes in 1966 on farm real estate and personal property amounted to $2.1 billion, up from $1.5 billion in 1960. Property taxes in 1966 amounted to 11.6 percent of the $17.9 billion net income for agriculture [20, p. 7]. Thus, real and personal property taxes represent a substantial charge against the entrepreneur's claim to farm income.[3]

---

[2] These societal reservations are not usually thought of in terms of reducing entrepreneurship of private landowners and operators. Yet, they do have such an impact. In discussing the conflict between public (social) and private (individual) rights, Dean Cribbet, College of Law, University of Illinois, suggested that "both private and public rights must give in an urbanizing society," and that "the legal tools are (a) police power, (b) eminent domain, and (c) taxation." (See *Proceedings of Rural Urban Fringe Conference,* Allerton House, Monticello, Illinois, November 9 and 10, 1967, p. 3).

[3] Between 1960 and 1966, the proportion of net farm income that went for taxes declined. This represents a decrease in entrepreneurship that was taken by taxes, which might indicate an increase in farmers' entrepreneurship between 1960 and 1966. The basic concern of this article, however, is not with shifts of this kind, although it does contain some ideas about them. The article is concerned exclusively with shifts in entrepreneurship from the specifications in the independent-farmer benchmark. Such shifts always represent a diminution in entrepreneurship, for the independent farmer, by definition, holds the maximum of entrepreneurship.

The taking by purchase of private property for public purpose eliminates completely an entrepreneur's use of the land; taking an easement only restricts his land use rights. Although detailed data are not available on the acreage or value of privately held farmland that may be taken for all public purposes, available data on future demands of the booming electrical transmission industry will furnish some insight. According to present plans (construction during 1968–75), 44,815 miles of new extra-high voltage transmission lines will reduce entrepreneurial rights in almost a million (986,820) acres of land [7, pp. 7–9]. The power of eminent domain doubtlessly will be exercised more frequently as population increases and urbanization and industrialization proceed.

The entrepreneur's right to use land as he chooses may be reduced by exercise of the police power. The police power is an inherent power of organized society to protect and encourage the public health, safety, morals, and general welfare. It is indefinable except in those terms. It is adaptable to the demands of new situations as they arise. Although all private land is subject to the police power at various levels of government, it is usually applied evenly to similarly situated farms. Rural zoning is one exercise of police power that affects agriculture.

Privately held land may become public land via escheat. This sovereign right merely fills the void when private ownership fails to supply a private owner. The incidence of escheat is small, for few landowners die without an heir.

The spending power of government is exercised in many programs that reduce entrepreneurship of the private landowner from that specified in the independent-farmer benchmark. The power of the purse is used to attain public policy objectives—for example, soil conservation, production control, and irrigation—that are not feasible under other reserved rights of the public in private lands.

The impingement of societal reservations upon a farmer's entrepreneurship may be beneficial—beneficial to society, as in property taxes, rural zoning, and public transportation, and to a particular farmer, as in soil conservation, irrigation development, and production control. Societal reservations are included here because they have an impact on the farmer's entrepreneurship. There is no suggestion that the use of societal reservations should be either increased or reduced. The *quid pro quo* aspect of the exercise of specific reservations, however, needs to be evaluated. Matters of equity become of increasing importance as the use of societal reservations expand.

Major Institutional Adjustments

Although societal reservations may continue to have an increasing impact on farmer entrepreneurship, greater changes probably will take place in institutional arrangements. Major adjustments may occur in form of organization, credit arrangements, lease agreements, production contracts, farmer cooperatives, and government programs.[4]

Form of organization

The independent-farmer benchmark is based on a sole proprietorship form of organization, in which the farmer may hold maximum entrepreneurship. Other conventional forms are: partnerships, in which entrepreneurship is usually divided among the partners; corporations, in which entrepreneurial functions may become widely diffused, failing grossly to meet the criteria of an independent farmer; and trusts, in which the trustee usually holds all farm and financial management control and may even dispose of the property, if the trust agreement so provides.

Most agricultural property is operated in sole proprietorships. Little information is available on farming corporations and the incidence of partnership and trust forms in agriculture is largely unknown. There probably are many partnerships in farming (for example, father-son partnerships). It is believed that the number of farm corporations has increased rapidly, particularly during the past decade. The Internal Revenue Service reports that there were 18,526 farming corporations in 1965 with business receipts of $4.9 billion, an average of $263,000 per corporation [22, p. 235]. In a survey of 22 states, Scofield and Coffman [18] found 6,700 corporations with agricutlural operations. These represented 0.7 percent of all commercial farms, and operated 6.8 percent of total acreage in all commercial farms [18, p. 10]. Data are not available on the use of farm trusts.

To understand the shift in entrepreneurship under the corporate structure, three types of farming corporations must be distinguished: (1) family farm corporations of the closely held Subchapter S type,[5] (2) large public corporations for farming only, and (3) large public corporations with the chief purpose of diversifying or reducing their income tax. When a family farm is incorporated, the operator can retain absolute control by owning over 50 percent of the voting stock. The farming corporation could place management control in one person, regardless of voting stock, but normally he would become a hired manager working under direction of the corporation, which would keep for itself many decisions, such as major policy formulation and disposition of the property. Although the corporate device permits a wide range in the allocation of entrepreneurial functions, some farms held by corporations and most farms held in trusts fail almost completely to meet the independent-farmer definition. Corporate and trust business forms generally represent the greatest departure from the independent-farmer benchmark. An exception may be the Subchapter S corporation.

---

[4] Minor institutional arrangements that effect entrepreneurship include professional farm management service, social security, workmen's compensation, and minimum wages. Others may be specified in a more detailed analysis.

[5] A Subchapter S corporation is one that is taxed like a partnership, avoiding the double taxation feature of the Internal Revenue Code for regular corporations.

Credit arrangements

Many farmers fail to meet the entrepreneurial attribute of the independent farmer of no encumbrances on either real or personal property. In 1967, farm real-estate debt was $23.3 billion and nonreal-estate debt was $22.4 billion, an indebtedness of $45.7 billion, or 17.0 percent of the total value of both real and personal assets of $269.5 billion used in farming [20, p. 2]. Brake estimated that debt-asset ratio would increase from 15.8 percent in 1965 to 28.4 percent in 1980 [5, p. 1542]. Credit may be used effectively to increase the total quantity of resources controlled by the farmer, but entrepreneurship may be diluted by provisions in the mortgage agreement.

What does this mean? Although credit is useful in acquiring control over resources needed to increase farm income, the diversion of several billion dollars annually to pay for debt capital weakens significantly the independent-farmer characteristic of unencumbered real and personal property. The diversion could also deplete income on heavily encumbered farms to the place that some farms would not meet the needs-of-the-family characteristic of the independent farmer. Credit, however, is essential in modern agriculture and plays an important role in efficient use of resources.

Some lenders are increasingly interested in the use made of loaned capital; in particular, many local banks are furnishing financial management along with their loans. A recent study reveals that over half of the agricultural banks of the country employ an agricultural specialist. Increasingly, they are requiring annual farm financial statements and budget or cash flow statements, and an increasing proportion are providing credit life insurance with farm loans and computer service to selected farm customers [2, pp. 5, 17, and 18]. The Farmers Home Administration of the U.S. Department of Agriculture has had considerable experience with "supervised credit."

To summarize, in 1967 farm entrepreneurs failed by $45.7 billion to meet the criterion of unencumbered property ownership. The resulting necessity of meeting high fixed annual charges reduced the entrepreneur's managerial freedom on many farms. In addition, an increasing number of lenders exerted some guidance and direction over farm operations of their borrowers.

surements were developed and data gathered to test the compatibility of family-operated farms with rapid technological advance.

Family-Operated Farms

Farm businesses of all sizes, large and small, are becoming larger. Although the increases are moderate, they reflect drastic changes in the structural organization of our farm economy. Under present economic and technological conditions, farms have to (1) reach larger, more adequate business sizes, (2) depend more on nonfarm income of operators and their families, or (3) disappear from agriculture. All three developments are proceeding at a rapid rate in this period of readjustment.

A sample survey by the Bureau of the Census estimated that in 1965 about 79 percent of all farm marketings came from farms with $10,000 or more of sales. It estimated that about 60 percent of the total income of operators' families came from sources other than the farms they operated [10]. In 1965 there were also about 1.8 million fewer farms than in 1949 (croppers' farms were not counted as independent units) and the decrease consisted mainly of family-operated units. This massive disappearance of family farms and the increase in the nonfarm income of farm families induced two conceptual errors often heard. The first is to equate family farms with small-size farm businesses, and the second, as a logical consequence of the first, is to interpret the disappearance of small farms as heralding the doom of the family farm [3]. However, the critical question is not how many small farms are disappearing, but whether more of these small units are being replaced by adequately-sized-family farms than by larger-than-family farms.

A shift of family farm labor to nonfarm occupations is also sometimes cited as evidence of a decrease in the importance of family farms. Here again, the critical question is not how much operators and their families are increasing their nonfarm activities, but whether they operate whatever they continue to farm mostly with their own labor and management. The answer to this question may be obtained by examining the changes in the proportions of family farms to all farms and in their shares of total farm production. These changes are of special significance for adequate family farms with $10,000 or more sales.[2]

---

[2] Adequate family farms are businesses with sufficient resources and productivity to yield enough farm income to provide for (a) expenses for family living; (b) farm expenses, including depreciation, maintenance of the livestock herd, equipment, land and buildings, and interest on borrowed capital; (c) enough capital growth for new farm investments required to keep in step with technological advance and rising levels of living. However, these are not the criteria by which adequate family farms were classified in this article. Here, family farms with $10,000 or more of sales were classified as adequate family farms. No implication was intended as to the efficiency of their production nor the adequacy of family income. It was recognized that family off-farm income often greatly contributes to the economic survival of a farm.

The salient facts of these changes are:

(1) Despite a marked reduction in the number of farms, the proportion that were family farms remained about the same from 1949 to 1964, and their share of marketings changed but little. In 1964, family-operated farms accounted for 95 percent of all farms and for 64 percent of the value of all products sold. In 1959, these proportions were 95 percent and 69 percent, respectively, and in 1949, 95 percent and 63 percent (Table 1).

(2) Family farms have been expanding rapidly in the hard core of our commercial agriculture—those units with $10,000 or more of sales, which today account for about 85 percent of total farm marketings. In 1964, there were 385,000 more family-operated farms with $10,000 or more of sales than in 1949. The adequate family farms accounted for 46 percent of total farm products sold in 1964, compared with only 21 percent in 1949. For the same period, the share of the total marketings of larger-than-family farms did not change. They accounted for 37 percent of all farm products sold in 1949 and for 36 percent in 1964 (Table 1; sales values in 1957–59 prices).

The economic importance of family farms varies greatly by states. Family farms are most dominant in the North Central part of the country, as well as in some of the Middle Atlantic and South Central states. In California, Texas, Florida, and a few other states on the other hand, family farms provide less than half of total farm sales (Figure 1).

Three observations may be made with respect to the regional differences:

(1) Family farms are most numerous where the mechanization of the farm production is at least as well developed as in any other part of the country. This indicates their compatibility with this kind of technological advance.

(2) In some types of farms, obtaining inputs, marketing, and processing have become so closely related to production that their organization is being readjusted to best coordinate these functions. Supplying inputs, marketing, and processing are stages of agricultural production more adapted to a concentration of capital, management, and labor than crop growing and animal production. As a result, these farms tend to develop into larger business sizes, and the patterns of organization found in nonfarm industries are becoming more prevalent. This is true of farms producing vegetables, fruits, eggs, and fed cattle—the leading products in California, Texas, Florida, and a few other states where family farms are less dominant. This suggests that regional differences are partly related to type of farming.

(3) However, there are also historical differences in the development of the structural organization of farming in these various regions. The family pattern of organization of the first colonists in the East and the

Table 1. Number and marketings of family farms as a percentage of all farms, United States, 1949, 1959, and 1964[a]

"Homestead" family settlement of the Midwest still influence these parts of the country. In the same way, the plantation system in the South and the Spanish latifundia heritage in California, Arizona, New Mexico, Texas, and Florida may still be factors in these areas.

Self-Employed Family Labor in Farming

Further light is thrown on the predominant family characteristics in the organization of our farming by examining data on the use of family labor and hired labor.

A classification of farms by use of hired labor shows that family labor is predominant on a majority of American farms, including a considerable number of relatively large units. It shows also that the greater part of national food and fiber is produced by family labor (Table 2).

Because of the substitution of capital for labor, the labor used on farms has declined rapidly. Today, about 70 percent less labor is needed to produce 36 percent more food and fiber than at the end of World War II. The crucial question with regard to family farms is whether this substitution of capital for labor has displaced more family or more hired labor [4].

In the last decade the proportions of work done on farms by family labor and by hired labor have not changed much. An analysis based on the wage bill shows that these proportions were 68 percent and 32 percent, respectively, throughout the 1960's. Bureau of Labor Statistics data show a somewhat higher proportion of family work done on farms, 70–71 percent. In an estimate based on a special survey by the Bureau of the Census, this figure rose to 72 percent between March 1965 and March 1966. Family labor accounted for 61 percent of all work done on farms with $10,000 or more of sales in the same period [11].

The long-term predominance of self-employment in American farming has not been lessened significantly by recent economic, social, and technological changes. As shown in Table 3, the proportion of self-employment on farms has remained about the same since 1930. In the country as a whole, family labor accounted for 76 percent of total farm employment during 1930-39 and 75 percent in 1967.

The alleged aging of farm operators is often taken as a sign of the shrinking importance of family labor in farming. The fact is that when farmers who are self-employed entrepreneurs are compared with their counterparts in other occupations, little difference is found in their ages. Farmers on adequate farms, however, tend to be younger than self-employed persons in nonfarm occupations [5].

Self-employment in farming varies greatly by regions. The highest proportion of self-employment, more than 86 percent, is found in the East North Central and West North Central geographic divisions. The smallest

and a decreasing proportion is found in California, Florida and Arizona, where family labor accounted in 1967 for only 36 percent, 31 percent, and 19 percent, respectively, of total farm labor. It should be noted that the decline in the proportion of self-employment in the southern part of the country was mostly due to a considerable decrease of croppers, who were classified as family labor. In the 1960's, when the outflow of croppers from farming in that region was about finished, the proportion of family labor again became stable (Table 3).

Operators' Management and Control of Production Resources

There is no available information that would permit a direct measurement of changes in the extent of operators' control over farm production resources, but general observations suggest that this control remains as strong as ever. However, continued control of farm operations and production resources does not mean that managerial functions are not changing. The following observations bear out these points.

Farms operated by paid managers

Since American farm production is primarily organized into family-operated farms, any reduction in operators' control would be reflected in an appreciable increase in the number and proportion of farms operated by paid managers. No such change has occurred. As a matter of fact, census data show a decrease between 1949 and 1964 in the number of farms with $2,500 or more of sales operated by paid managers, with no significant change in the proportion of all farms in that category. More important, it appears that the same is true for the proportion of managers' farms in all economic classes of farms, including the largest group with $100,000 or more of sales, where the corporate form is found (Table 4).

Farms operated by paid managers are heavily concentrated in Califor-

nia and Florida and are of considerable economic importance in Arizona, Nevada, and Connecticut. In 1964 marketings by farms operated by paid managers accounted for 35.4 percent of all sales by commercial farms in Florida, 20.4 percent in California, 26.8 percent in Arizona, 26.0 percent in Nevada, and 23.1 percent in Connecticut. But these states, as already shown, were never the strongholds of family farms. On the contrary, larger-than-family farms were always of great economic importance. In the rest of the country, farms operated by paid managers are of much less importance. In the Corn Belt, for example, sales by farms under paid management accounted in 1964 for less than 3 percent of total farm marketings (Figure 2).

Land tenure

A significant expansion of large farm businesses, and their substitution for family farms, would be reflected in a considerable increase in the proportion of acreage operated under paid management. But no changes have been evident in traditional land tenure patterns in the United States.[3] Throughout the last two decades, from 1944 to 1964, the proportion of land operated by owners has been about 55 percent; by renters, 35 percent; and by paid managers, about 10 percent (Table 5).

In United States agriculture, farmers have traditionally owned most of the machinery needed in farm production and they continue to do so. Parsons [7] states that in 1956, "considering all farms in the United States,

---

[3] We are speaking here of the tenure under which farmland is operated, disregarding the composition of operating units. Thus, for example, in a part-owner farm, part of the land is owned by the operator and part is rented.

only a few machines, such as pickup haybalers, field forage harvesters, and power dusters, show independent ownership below 80 percent." For most other machines 90 percent or more were independently owned by farmers. In 1964, according to Strickler and Smith [9] "most of the cultivating of crops and land—94 percent—was done by farmers with their own equipment." Even in combining crops, where custom work was always most prevalent, farmers' own equipment continues to predominate. Of the 153 million acres that were combined in 1964, 72 percent were harvested with farmers' own equipment [9].

Managerial functions changing

General observations indicate that neither the importance nor the basic managerial functions of farm operators have been diminished, although most of these functions have greatly changed in nature. Farm operators are still in control of nearly all resources used in farm production and they still control these resources mostly through ownership.

How to organize and use their equities and other resources are the main managerial decisions that a farm operator makes, just as he always did, whether the farm is large or small. In either case, the operator remains the risk-taking manager who commits his work, his managerial skill, and the capital he owns or controls to a production enterprise in order to make a living by selling and/or consuming its output. With respect to his independence as an entrepreneur, it makes no difference whether he negotiates prices for specified products in advance or does so in an open market after they are produced.

While recent structural changes in the farm economy have not changed the farm operator's basic decision-making function, they have greatly changed his other managerial functions. He performs fewer managerial functions in the marketing of farm products and in the implementation of much of the technology used in farm production. Some of his production risks have been shifted by government farm programs and by the increasing involvement in farm production of food processors, feed dealers, and other farm suppliers. Furthermore, more and more managerial services are available to farmers in their farming operations. For example, not long ago the fertilizing of farmland required important managerial decisions by the farmer, drawing greatly on his skill and experience. Today these decisions are less difficult—a telephone call to any well-organized fertilizer dealer can bring competent and valuable help. On the other hand, farmers now have to buy many more inputs and thus require more operating capital. Some management decisions, therefore, have become more complex and more risky, requiring more skill, ingenuity, and knowledge in many new fields.

It appears that the outgoing managerial functions of the farmer are more than offset by incoming ones. His economic importance is definitely increasing, both as seller and as buyer. In 1967 farm production expenses were $33 billion, almost double the $17 billion of 1949; and sales of farm products in 1967 were $41 billion, compared with $27 billion in 1949 (all values expressed in 1957–59 prices). These increasing farm activities are not indicative of any lessening in the importance of farmers' managerial functions.

Concentration of Farm Production

If technology were destroying the family pattern of farm production, as it did in many other commodity producing industries, we would most likely be witnessing a concentration of farm production, farmland, and other productive resources into an increasingly smaller number of large farming organizations. Not so. Farm production, farmland, and other production resources are concentrating—but in a rapidly expanding number of adequate farms of medium and large size (Table 6) [6].

Three additional observations are of special interest with respect to this concentration of farm production. First, farms continue to be mostly family-owned businesses. Income tax return data show that, in 1965, of 3.2 million businesses reporting receipts from farming, 95.9 percent were sole proprietorships; 3.6 percent, partnerships; the remaining 0.5 percent, corporations.

Second, farms continue to be relatively small businesses. While some units may be large in relation to others, and larger than they were before, they are still hardly comparable to the sizes of most other American pro-

duction organizations. As a matter of fact, on the basis of present standards used by the Small Business Administration in determining the eligibility of firms for assistance, few farms would be large enough even to qualify as small businesses. Farm production is organized into more and smaller businesses than any other major group of industries or services.

Third, although part-time farming units and small units with less than $20,000 of sales are not very productive, and definitely are not the commercial farms of the future, they are today still an important part of our farm economy. In 1967 2.6 million small farms with less than $20,000 of sales accounted for about 15 billion of farm products sold—32 percent of total sales—and for approximately 7 billion of realized operators' net farm income—48 percent of all farmers' net income.[4] More than 90 percent of our farm population, about 9 million persons, live on these small and part-time farming units. This is a characteristic aspect of our farm economy, and its economic and social significance can hardly be overestimated.

Conclusions

Why then has the techological explosion in farming not destroyed the family and self-employment characteristics in the organization of farm production in most of the United States and its farming enterprises? The biological nature and the spatial dispersion of farm production may be largely responsible, for they make a large concentration of capital, management, and labor more difficult in farming than in other industries. Thus, competitive efficiency (least-cost production) is attained in farming at a smaller firm size than in many other kinds of production, and these smaller sizes in turn are being adapted to the managerial and working capacities of self-employed family labor.

As yet, no technological breakthrough has significantly eliminated the considerable influence of biological and spatial characteristics on the organization of farm production. Farms remain mostly family-operated, family-owned, and relatively small businesses. The coexistence of family and larger-than-family farms, in about the same proportions, continues to characterize the organization of farm production.

However, great changes have been taking place. The present family farms and larger-than-family farms only remotely resemble the family and larger-than-family farms of the past. Farm production is becoming increasingly specialized—concentrating on specific crops and livestock. Farms are becoming more dependent on nonfarm industries for production inputs and for marketing. Some farms have changed so much that we hesitate to call them farms any more. The emphasis on farm ownership is also changing. While farm real estate and farm inventory ownerships remain as strong as ever, the ownership of the farm business itself and many contractual "rights-ownerships" are playing an increasingly more important role in modern farming. For example, a farmer may own rights on the basis of a lease, contract farming arrangement, custom work, or any other operational or financial contract. Many managerial functions are shifting away from farms. Again, many entrepreneurship risks that farmers had to bear only a few decades ago are now lessened by government programs and by contract farming, which tend to insure against extreme commodity price fluctuations and provide market stability. However, farmers face greater risks in their increasing use of capital and credit.

---

[4] In 1964 farms with less than $20,000 of sales accounted for 51 percent of all corn produced, 54 percent of all wheat, 79 percent of all tobacco, 50 percent of all milk sold, and 32 percent of all cattle and calves sold.

Changes—radical changes—are the order of the day in agriculture; and their study, in all aspects, should be the main task of our professional endeavors. However, despite all these changes, many characteristics of the organization of the farming industry remain basically unaltered. May I suggest that one of these, the coexistence of family farms and larger-than-family farms in their traditional regional locations, is likely to stay with us for a long time to come.

A Production-Investment Decision Model of Farm Firm Growth*

MICHAEL D. BOEHLJE AND T. KELLEY WHITE

This article presents the conceptualization of a farm firm growth model which includes both investment and production decisions. The results obtained in the application of the model to a hypothetical Central Indiana farm under alternative resource availability and optimizing criteria assumptions are reviewed. These applications demonstrate the interaction between investment and production decisions in the growth process and indicate that under realistic conditions optimal firm growth is not scale growth. They also indicate that the growth process and the terminal size are different for different objective functions. Finally, the results illustrate the applicability of such a model for investigating farm firm adjustments in a growth context.

THE development of micro-economic models which explicitly include the time element has greatly increased our ability to analyze the process of firm growth. Because of rapid growth or changes in size and organization of farm firms, agricultural economists have attempted to develop operational models that explain and predict these phenomena. This article presents the conceptualization and application of a farm firm growth model that includes both investment and production decisions.

Combining Production and Investment Decisions

Three methodologies have been proposed in the literature to combine production and investment decisions in dynamic models to study firm growth: simulation, dynamic programming, and multi-period linear programming.[1] Simulation models developed by Patrick [22] and Harshbarger [10] have been used to evaluate the impact of managerial ability and capital structure on farm firm growth, assuming non-stochastic and stochastic yield and price variations. Harl [9] has used a simulator to evaluate the impact of business organization (sole proprietorship, regular corporation, etc.) on farm firm organization and expansion.

Although dynamic programming has been applied to problems of replacement and feedlot management [14, 23], to our knowledge this methodology has not been applied to the problem of growth of the total farm firm. However, Minden [20] has conceptualized the firm growth problem in a dynamic

MICHAEL D. BOEHLJE *is graduate research assistant and* T. KELLEY WHITE *is associate professor of agricultural economics at Purdue University.*

programming framework and has discussed various advantages and disadvantages of this technique.

Examples of the utilization of multi-period linear programming models to study growth problems are much more abundant. Following Dorfman's discussion of the applicability of linear programming to multi-period problems [7], Swanson [24] and Loftsgard and Heady [17] developed the first multi-period planning models. Following in quick succession were applications by Irwin and Baker [13], which concentrated on intra-year financial transfers, and Barr and Plaxico [1], which emphasized capital flows among years. In an aggregate study, Cowling and Baker [4] used multi-period linear programming to estimate regional milk supply of growing dairy farms. Dean and Benedictis [6], Martin [19], Johnson [15], Eidman, Carter, and Dean [8], and Cocks and Carter [3] have more recently made additions to the literature in this area.[2]

Most of the recent work in the application of multi-period linear programming to firm growth has concentrated on the investment decisions, growth rate, and terminal size. For example, Dean and Benedictis, who treat production decisions in more detail than most of the other studies, exogenously determine aggregate annual production activities and make orchard establishment an irreversible decision [6, pp. 299, 302]. Both Martin and Johnson assume a single predetermined aggregate production activity for each time period, and the production activity is the same for all time periods. Thus, the only production decision that must be made each year is the magnitude of the one production activity.

Treating the organization of production as an exogenous and irrevocable decision in a firm growth model seems reasonable if: (1) linear relationships are assumed; (2) one is analyzing the firm in a long-run context where, by definition, all factors of production are variable; (3) all factors, including types of credit, are available in unlimited quantities or, if limited, are available in constant proportions; and (4) relative prices and technology are constant. Under these conditions the firm would be able to generate the largest quantity of investment funds each year by determining the most profitable combination of factors of production and products, acquiring the optimum quantity of the combination of factors, and producing the optimum quantity of the combination of products. Thus, all changes in size of the production unit would be scale changes.[3]

It is important to consider organization decisions or decisions concerning production and annual labor and capital acquisition as an integral part of the growth process when the above conditions are not a reasonable approximation of reality. The existence of resource fixities during specified periods of the planning horizon may cause the optimal production organization to change from period to period as the fixities change. Institutional restrictions may cause the relative availability of particular classes of resources to differ at any point in time and to change over time. For example, credit that can be used to acquire annual inputs may be available in unlimited quantities if its proposed use can be shown to be profitable, while credit that will be used to purchase durable inputs may be limited to a specified proportion of the firm's net worth.[4] Thus, the availability of durable inputs may be more restricted than the availability of annual inputs during any particular period, and the relative availabilities of these inputs may change as net worth increases. Similarly, the farmer's ability and willingness to manage hired labor may place a limit on the labor supply the firm will utilize. This limited labor utilization combined with an increasing supply of capital may allow substitution of capital for labor, resulting in changes in the optimum organization of the firm over time.

---

[2] Applications of recursive linear programming to the firm growth problem have been made by Day [5] and Heidhues [11].

[3] Even if the above conditions do not hold, external factors such as government programs or climatic and soil conditions may make exogenous production decisions realistic if they limit the firm to the production of one product with only one type of technology. See Martin [19].

In the following discussion, the conceptualization of the growth process is presented verbally, in equation form, and in matrix form. The growth model is then applied to a corn-hog farm typical of Central Indiana and comparisons are made between the growth processes that occur under different assumptions of labor availability. Finally, the expansion processes resulting from two different objective functions are analyzed. The discussion emphasizes the process of growth (the optimal combination of enterprises, techniques of production, and investments over time) under different resource assumptions and objective functions rather than concentrating on the terminal values of the growth variables.

The Growth Process

As conceptualized in this study, growth is made possible through the generation of investable funds.[5] Two sources of investable funds are available to the firm in any time period. First, disposable income in excess of consumption requirements increases the availability of funds in the following period.[6] Second, the firm may borrow funds. The borrowing capacity (total debt load) of the firm during any period is a function of net worth at the end of the previous period. Permissible *new* borrowing in any period is the difference between borrowing capacity and outstanding debt. The firm's borrowing is also constrained by the ability to service debt out of future income.

---

[4] Irwin and Baker [13] and Neuman [21] indicate that lending institutions tend to place less emphasis on collateral for short-term loans than for longer-term loans.

[5] Growth may be defined as an increase in the size of the firm. In this study, growth is measured by change in net worth and disposable income.

[6] Disposable income is defined as net revenue above variable costs less debt servicing (principal plus interest).

The generation of investable funds from both internal and external sources increases the ability of the firm to acquire additional durable inputs (land, machinery, buildings and facilities). The productive capacity of the firm is increased by the acquisition of these additional durable inputs, and this increased productive capacity can be used to produce a larger quantity of output. Finally, a higher level of output will result in a higher level of disposable income and/or increased net worth depending upon the objective of the firm.

Production and investment decisions are interdependent over time in the growth process. Thus, current optimal production and investment decisions are dependent upon past production and investment decisions, as well as future production and investment opportunities.

The Conceptualized Farm Firm Growth Model

The above conceptualization of the growth process now is presented in equation form. The notation used in the following equations deviates from standard linear programming notation in that only the production activities are denoted by the symbol X_{jt}, the jt subscripts indicating a specific activity and a time period, respectively. To emphasize their difference from the production activities, other specialized activities are denoted by capital English letters (for example, I_{jt} denotes investment activities, S_{jt} denotes sale activities, etc.). Constraints are also identified by capital English letters, but with ik subscripts rather than jt. Ranges on the activities and constraints are denoted by small English letters. All coefficients are identified with Greek letters.

Two time subscripts are incorporated in the model, one for the period of the decision and one for the period of accounting. The decision period is denoted by the subscript t and is usually carried on all activities. The accounting period is denoted by the subscript k and is usually carried on all constraints. When the accounting period and the decision period are the same, it is indicated in the equation by the subscript $k=t$.

The following equations specify the firm growth process:
Maximize: Discounted Disposable Income

$$(1)\quad \underset{\substack{\text{(present}\\ \text{value dis-}\\ \text{posable}\\ \text{income}\\ \text{stream)}}}{DI'} = \sum_{t=1}^{T} \underset{\substack{\text{(sum of discounted annual dis-}\\ \text{posable income)}}}{\frac{\sum_{j=a}^{d} \eta_{jt} X_{jt} + \sum_{j=v}^{x} \eta_{jt} Y_{jt} - \sum_{j=e}^{g} D_{jt}}{(1+\rho)^{t}}}$$

or

Maximize: Net Worth (with $k = T$)

Subscripts:[7]

j = the activity, $j = a \ldots z$;
i = the input constraint, $i = a \ldots z$;
t = the period of the decision, $t = 1 \ldots T$;
k = the period of accounting, $k = 1 \ldots T$.

Coefficients:

η_{jt} = the annual return above variable cost of one unit of activity j in period t;
ρ = the interest rate used for discounting disposable income;
τ_j = the investment or sale *price* of asset j;
β_{jt} = for assets, the years owned or the depreciable life, whichever is less, of the jth asset purchased in period t; for loans, the years the loan has been serviced or the loan maturity, whichever is less, of the jth type of debt incurred in period t;
δ_j = rate of annual depreciation for asset j;
θ_{jt} = years of depreciable life of asset j between year of sale (t) and year of accounting (k);
γ_j = principal repayment rate on borrowing of type j;
α_{ijt} = the amount of resource or capacity of type i necessary to satisfy one unit of the production activity of type j in period t;
σ_{jt} = for asset j purchased in period t, equal to zero if obsolete or one if not obsolete; for borrowing of type j in period t, equal to zero if mature, or one if not mature;
ξ_{ijt} = the quantity of liquid capital of type i necessary to purchase one unit of asset or off-farm investment j in period t, $(\Sigma_{i=e}^{h} \xi_{ijt} = \tau_j)$;
λ = proportion of net worth that can be borrowed;
ρ_j^* = the rate of interest on debt of type j;
ψ = the marginal propensity to consume.

Decision variables:

X_{jt} = the level of production or annual input acquisition activity j in period t;

---

[7] Definitions of subscripts, coefficients, and variables are listed in the order of appearance of the terms in the model.

D_{jt} = the dollar amount of debt servicing of type j in period t;
I_{jt} = the level of investment in durable asset j in period t (physical units);
S_{jt} = the level of sale of durable asset j in period t (physical units);
T_{jt} = the level of annual income transfer of type j from period t to period $t+1$;
Y_{jt} = the level of off-farm investment of type j in period t;
N_{jt} = the level of borrowing of type j in period t.

State variables:

DI' = the present value of the stream of disposable income;
NW_k = the net worth of the firm at the end of period k;
$\overline{NW}_k$ = the net worth at the beginning of period one minus initial cash balance and depreciation to year k (exogenously determined);
B_{ik} = the physical amount of resource i available in period k;
$\overline{B}_{ik}$ = the amount of the initial endowment of resource i adjusted for obsolescence to period k (exogenously determined);
M_{ik} = the amount of liquid capital of type i available in period k;
$\overline{M}_{i1}$ = the amount of initial endowment of liquid capital of type i (exogenously determined and available in the first period ($k=1$) only);
Z_{ik} = the amount of principal and interest on debt of type i due in period k;
$\overline{Z}_{ik}$ = the amount of principal and interest on initial outstanding debt of type i that must be serviced in period k (exogenously determined);
DI_k = the amount of annual disposable income generated in period k;
F = the minimum consumption level ($3,000).

Two alternative objective functions are incorporated in the model. The first objective function maximizes the present value of the annual disposable income stream. Present value of disposable income, equation (1), is the sum of the discounted annual disposable incomes over the planning horizon.[8] Annual disposable income, equation (11), is defined as annual net revenue above variable costs from farm production and off-farm investments less annual debt servicing (principal plus interest). Thus, it is the quantity of funds available for consumption, payment of income taxes, reinvestment in the firm, and investment outside the firm.

The second objective function, equation (2), assumes the maximization of the net worth of the firm at the end of the planning horizon. Net worth in period $k=T$ is defined as the net worth at the beginning of period one, adjusted for initial cash balance and depreciation to year T, plus the total new investment in durable assets to year T, minus the total accumulated depreciation of these assets,[9] minus sale of assets through period T,[10] plus adjustment for depreciation on assets sold through period T,[11] plus the amount of cash transferred to the next period, plus the value of the off-farm investments in period T, minus the net borrowing to year T (total borrowing minus repayment of principal).[12]

---

[8] A time preference and risk discount factor of $1/(1+.10)^t$ was assumed.

[9] Because the investment term in this equation $(\Sigma\Sigma_{jt}r_jI_{jt})$ accumulates new investment, the

The technical and institutional constraints on the objective functions are summarized in equations (3), (5), (7), (8), and (10). Production capacity is constrained in any period by the quantity of resources available, as indicated by equation (3). The quantity of resources available, equation (4), is defined as the endowment at the beginning of period one, adjusted for obsolescence, plus accumulated new investments adjusted for obsolescence (if a specific I_{jt} is obsolete, its $\sigma_{jt}=0$), minus sales of durable assets. The dollar amount of durable assets and off-farm investments that can be acquired in any period is limited by the amount of liquid capital available in the period, equation (5). Available liquid capital in any period is defined by equation (6) as the sum of borrowing in that period, the liquid capital transferred from the previous period, liquid capital invested outside the firm in the previous period, and capital obtained from the sales of durable assets.

Permissible new borrowing in any period is total borrowing capacity minus outstanding debt, with total borrowing capacity being a function of net worth, equation (7). The debt servicing requirement is identified by equation (8), with the debt servicing schedule, equation (9), defined as principal and interest payments on the outstanding debt at the beginning of period one plus principal payments on incurred debt that hasn't matured (if a specific N_{jt} has matured, $\sigma_{jt}=0$) and interest on the unpaid balance of debt incurred through the present year. Finally, the amount of funds that can be transferred to the following period is defined by equation (10) as the annual disposable income minus annual consumption.[13]

---

depreciation term ($\Sigma\Sigma_{jt}\beta_{jt}\delta_j\tau_j I_{jt}$) must reduce this gross investment figure to net investment. The β_{jt} coefficient equals either the years the asset has been in service or the useful life of the asset if its serviceable life is over. Thus, if a depreciable asset has completely deteriorated, the total depreciation of this asset equals the purchase price.

[10] Because receipts from sale of assets add to liquid capital that can be reinvested, the value of sales must be deducted to avoid double counting.

[11] Since the depreciation term in this equation ($\Sigma\Sigma_{jt}\beta_{jt}\delta_j\tau_j I_{jt}$) accumulates depreciation on all assets from the year of purchase to year k or until the item is fully depreciated, it is necessary to adjust accumulated depreciation for assets sold through period k. This is the function of the term ($\Sigma\Sigma_{jt}\theta_{jt}\delta_j\tau_j S_{jt}$) where θ_{jt} is the number of years of depreciable life between the year of sale (t) and the year of accounting (k).

[12] The β_{jt} coefficient plays the same role in the principal repayment term ($\Sigma\Sigma_{jt}\beta_{jt}\gamma_j N_{jt}$) as it did in the depreciation term. It equals either the years since the loan was made or the maturity if the loan has been repaid.

[13] A minimum annual consumption of \$3,000 was specified. In addition to the minimum consumption level, a marginal propensity to consume 50% of all disposable income above \$3,000 was assumed. This consumption function is postulated to meet family requirements plus income taxes.

The Model in Matrix Form

Table 1 illustrates a two-period growth model in linear programming matrix form. The decision variables included in each subset of activities have been defined. The numbers in parentheses after the constraints refer to analogous equations in the conceptual model. The A_{ijt}'s ($t=1, 2$) indicate submatrices of coefficients relating the activities and the constraints.

The C_{jt}'s ($t=1, 2$) in the objective function accumulate the value of the variable being maximized. When discounted disposable income is maximized, C_{jt} coefficients ($t=1,2$) in the division of income activities accumulate the entire amount of discounted annual disposable income in the objective function. If the C_{jt}'s in the division of income activities in Table 1 are eliminated and replaced by a $C_{jt}=1$ in the net worth activity for the last period in the planning horizon, the objective function is transformed from maximizing present value of disposable income to maximizing terminal net worth.

It should be noted that the annual disposable income equation is included in the model as an accounting equation when net worth is maximized, equation (2), and annual net worth is included as an accounting equation when discounted disposable income is maximized, equation (1). Thus, total farm size and growth can be measured in terms of either disposable income or net worth regardless of the objective.

Application of the Model

The multi-period linear programming model was applied to a hypothetical farm firm assuming a ten-period planning horizon.[14] Each period comprises one calendar year. Technical coefficients and input and product prices were assumed to be constant throughout the 10 years. Since the objectives of the study were to analyze the impact of resource availability and different optimizing criteria on farm firm growth, incorporating technical coefficients and prices as variables would not allow one to isolate the relationship between resource changes, optimizing criteria and growth. The technical coefficients and prices were assumed to be those that exist for high level managers at the present time and were acquired from various farm management research and extension publications.

The initial resource endowment assumed and the production alternatives considered are typical of a small corn-hog farm of Central Indiana. The endowment consisted of 160 acres of cropland, sufficient machinery and equipment to produce row crops on the land, facilities to accommodate the

---

[14] A simultaneous solution multi-period model, as used in this study, results in a global optimum by solving for all periods in the planning horizon simultaneously. Conversely, a recursive multi-period model is solved for each period independently of all future periods (with the output from the period t being used as input for the period $t+1$). Thus, the recursive model does not allow for the allocation of resources among periods, and suboptimization may result.

Table 1. The multi-period linear programming matrix

	Period 1				Period 2

labor intensive production of 40 two-litter sows per year, one man-equivalent of operator labor, and the opportunity to hire an additional man-equivalent of labor. The owner-operator was assumed to possess a 40 percent equity in the assets of the firm.[15]

Alternative production activities incorporated in the model include both labor and capital intensive corn and hog enterprises as well as soybeans, wheat, dairy and beef-feeder enterprises. In addition, the matrix for each year contained investment, credit, debt servicing, land renting (in and out), external investment, and income transfer activities. In all, 79 activities and 44 constraints were specified for each year, resulting in a triangular matrix for the 10-year planning horizon with 790 columns and 440 rows.

Analysis of the Growth Process

The growth process resulting from the application of the growth model to the hypothetical farm firm is summarized in Table 2, which indicates

Table 2. Summary of the growth process of the farm firm assuming one man-equivalent of hired labor and disposable income maximization

Year	Corn[a]	Corn[b]	Hogs[c]	Hogs[d]	Hogs[e]	Hogs[f]	New borrowing	Disposable income[g]	Net worth
	acres		sows[h]			pigs	intermediate-term[i]	dollars	
1	160		48				2,503	8,630	65,628
2	160		71				3,835	11,811	77,181
3	151	13	111				7,466	19,896	91,627
4		101	144				6,804	21,576	108,338

6		114	120	15	16			26,382	142,466
7		125	120		34	469		31,150	159,353
8		125	120		34	1,311		36,004	176,812
9		125	120		34	1,985		38,506	185,904
10		127	107	13	37	2,833		42,280	195,747

[a] conventional tillage
[b] minimum tillage
[c] labor-intensive technique, farrow and finish on pasture
[d] mixed technique, farrow in confinement and finish on pasture
[e] capital-intensive technique, farrow and finish in confinement
[f] labor-intensive, purchase and finish feeder pigs on pasture
[g] These quantities are *not* discounted. The quantity of internally generated capital available to invest in the following period can be calculated by the following formula:
Internal capital available for time period $k = .5$ (Disposable Income $_{k-1}$ —$3,000).
[h] 18 pigs/year/sow
[i] dollars

---

[15] The beginning asset-liability structure was determined by valuing long-term assets (land) and intermediate-term assets (machinery, buildings, and facilities) at purchase price minus depreciation and then giving the owner a 40 percent equity and 60 percent liability in each class of assets.

the annual enterprise organization, borrowing, disposable income, and net worth for each of the ten periods when discounted disposable income is maximized.

Hog and corn production enterprises dominate the firm organization during the entire planning horizon. However, changes in relative size as well as production technique occur in these enterprises. These are explained by changes in the relative availability of resources resulting from the assumed restrictions on labor hiring, the internal generation of capital and the deterioration of initial endowments of machinery and livestock facilities.

The size of the corn enterprise remains relatively constant during the first three years of the planning horizon. By the fourth period, the initial endowment of conventional tillage machinery has completely deteriorated and the upper limit on labor acquisition has been attained. As a result, minimum tillage equipment is purchased (thus substituting capital for labor in corn production) to produce 101 acres of corn, and the remaining owned land is rented out. This capital-intensive production technique continues to dominate the corn enterprise for the remainder of the planning horizon, but continued competition from the hog enterprise for both labor and capital restricts growth of this enterprise.

The hog enterprise expands rapidly throughout the planning horizon. Investment is made in labor-intensive production facilities for the first four periods until labor becomes limiting, and then a transition begins from labor-intensive to capital-intensive farrowing-finishing of hogs. However, investment in labor-intensive finishing facilities continues during the remainder of the planning horizon to provide capacity for the finishing of feeder pigs, an operation that utilizes free labor during the first four months of the year.

The expansion of the hog enterprise during the early years requires utilization of capital in addition to that generated internally, and all available intermediate-term credit is acquired during the first three periods. By period five the marginal value product of a unit of external capital is lower than the marginal factor cost and thereafter only internally generated funds are used for new investment. No long-term debt is incurred during the entire planning horizon.

As indicated in Table 2, both the disposable income and net worth of the firm increase throughout the planning horizon. By the tenth year, the net worth of the firm has almost tripled and annual disposable income of $42,280 is generated.

Impact of Labor Availability

The growth processes resulting from two different levels of labor availability were compared to examine the impact of this resource on farm firm growth. Both levels assumed one man-equivalent of operator labor to be available in all years. In addition, labor could be hired, when profitable to do so; but only one man-equivalent could be acquired under assumption I whereas three man-equivalents of labor could be hired under assumption II. The initial availability of all other resources was assumed to be identical.

The firm organizations generated under both labor assumptions are identical during the first three years. However, beginning in year four, the upper limit on labor hiring is attained under assumption I and differences in labor availability result in different growth paths. The ability to acquire more labor results in the utilization of more credit and thus facilitates the more rapid expansion of the productive capacity in both the hog and corn enterprises. The transition from labor-intensive to capital-intensive hog production occurs later in the planning horizon when three man-equivalents of hired labor are available. In fact, the production of hogs in capital-intensive facilities remains quite insignificant throughout the planning horizon under the less restrictive labor assumption.

The availability of labor also influences the timing of external capital utilization. Intermediate-term capital is borrowed during more periods when more labor is available; but under both labor assumptions, new capital borrowing is discontinued during or immediately following the period when the upper limit on labor acquisition is attained.

Higher levels of annual disposable income are generated when labor availability is less restricted. The generation of more disposable income results in a larger amount of liquid capital that can be invested in the following year and, thus, higher levels of investment, capital stock, and net worth during successive years.

Comparison of Two Optimizing Criteria

A comparison between two potential optimizing criteria or goals of the farm manager was obtained by incorporating in the model two different objective functions having identical initial resource endowments. These functions were (1) maximization of the discounted stream of disposable income over the planning horizon and (2) maximization of net worth at the end of the planning horizon. Results obtained under the first objective function were presented earlier in Table 2. The results obtained when net worth is maximized will now be contrasted with the earlier results.

After the third year, substantial differences occur in the enterprises included in the firm organization under the two criteria.[16] The corn enterprise is eliminated from the organization and the owned land is rented out during the fourth year when net worth is maximized, because machinery is not replaced as it deteriorates. After year six, the production of hogs in capital-intensive facilities expands much more rapidly under the net worth criterion. However, much of this production occurs in mixed production facilities where either the farrowing or the finishing occurs in capital-intensive facilities and the other operation occurs in labor-intensive facilities.

---

[16] These results are in contrast with those presented by Martin [19] where different objective functions result in the same firm organization and firm size. One explanation for the differing conclusions is that our study incorporates a more complete specification of investment and production alternatives, allowing for factor substitution, whereas Martin's study does not allow factor substitution. In addition, the disposable income objective function used in this study does not correspond to any of Martin's objective functions.

Differences in the investment and credit components of the firm organization provide the most interesting comparisons between the two objective functions. No long-term credit is employed in any year and new intermediate-term credit is acquired only through the fourth year when the disposable income criterion is used. In contrast, all available long-term and intermediate-term credit is utilized during the entire planning horizon when the net worth criterion is used. Under this criterion, borrowing in period 10 is limited not only by the firm's net worth but also by the ability to service debt, since disposable income is reduced to the minimum consumption level.

The two maximization criteria result in different investment strategies relative to the durability of assets purchased. When the disposable income criterion is used, all the assets purchased are depreciable assets, such as buildings and machinery. Under the net worth criterion, the major asset purchased is land. By the tenth year, 385 acres of land have been acquired and added to the 160 acres included in the initial endowment. None of this land is tilled by the operator. Instead, it is all rented out because the return to labor and intermediate-term capital in hog production is greater than in crop production.[17]

The annual disposable income generated under the net worth optimizing criterion remains consistently below that generated under the disposable income criterion, indicating the much larger debt servicing payments that must be made when more credit is utilized. However, substantially more net worth is generated when the net worth criterion is used. Thus, differences in the rate of growth may be explained by different objective functions as well as by the use of different variables to measure growth.

Implications for Firm Growth

The empirical results indicate that in all cases the farm becomes more concentrated in the production of hogs, the most profitable enterprise, as it expands over the ten-year period. These results are consistent with the current trend in midwestern agriculture toward specialization and indicate that this specialization is a logical attempt by farm managers to expand their operations as rapidly as possible.[18]

---

[17] For a more complete explanation of this phenomenon, see Boehlje [2, pp. 149–151]. pp. 149–151].

[18] Some would argue that specialization in crops is more typical than specialization in livestock in the Midwest. Obviously, the prices and technical coefficients assumed will influence the area of specialization.

The growth process also consistently included the substitution of capital for labor as the availability of labor became more restricted and capital availability increased. Not only is this capital-labor substitution consistent with current trends, but it also indicates that institutional and behavioral restrictions on the availability of resources *may be* as influential as relative price changes in causing resource substitutions.

During the early periods of the planning horizon, high shadow prices exist on the credit restrictions and the capital resource. These high shadow prices indicate that institutional credit restrictions based on collateral rather than the expected profitability of the investment limit the early expansion of the firm.

The substitution of capital for labor and the enterprise changes also illustrate the necessity to consider investment and production decisions interdependently. Thus, it is important for the agricultural producer to increase his planning horizon beyond the current production period if he expects to make optimal investment and production decisions.

The comparison of the two optimizing criteria indicates the impact of alternative growth strategies. When net worth is maximized, a heavy debt load is incurred and the amount of disposable income available to satisfy farm family consumption is restricted. In contrast, the objective of maximizing disposable income results in the generation of substantially less net worth, but much less credit is used and more income is available for consumption. Consequently, under the assumptions of this study, it can be concluded that the objective of maximizing net worth will generate a greater value of owned assets, but farm family consumption must be sacrificed and a more vulnerable debt position is acquired.

Implications for Further Research

The inclusion of both capital-intensive and labor-intensive production activities and related investment activities enables this model to consider capital-labor substitution in a production-investment framework. This flexibility allows the model to generate realistic results as relative resource availability changes over time. Price changes, price trends, and trends in technical coefficients were not incorporated in the model; but they could easily be included and would provide valuable information on the impact of price variability on the growth process.

As indicated by Walker [25], one of the major limitations of the multiperiod linear programming formulation of the growth process is the difficulty of incorporating elements of risk and uncertainty in the model. Consequently, outcome of future periods is known with certainty when the organization of earlier periods is determined. Walker suggests that solving a simultaneous multi-period model in a recursive manner with updated coefficients might be one method of skirting the problem of risk incorporation and might be a more realistic approach to the decision-making process [25, p. 1527]. Alternatively, Johnson, Tefertiller, and Moore [16] have incorporated a distribution of crop yields in a deterministic linear programming model to demonstrate the impact of random variations in yield on firm growth. Additional research is needed to find a realistic and feasible way of treating risk and uncertainty in firm growth models of the type presented in this paper.

Although income taxes were considered in the model, the procedure used was quite naive. Income, property, and real estate taxes are important variables in formulating growth strategies and a further extension of this model could incorporate these variables as decision variables.

Finally, the results of this study raise the issue of whether profit maximization is the long-run goal of managers. According to Lutz and Lutz [18], net worth maximization is consistent with profit maximization. The maximization of discounted disposable income is analogous to the cash flow arguments of the business school. Interestingly enough, the disposable income criterion generates more realistic results than the net worth criterion. Further behavioral research may indicate that this is characteristic only of this particular model, or that the arguments and concepts of the business school more accurately describe farmer behavior than do those of the economic theoretician.

Sources of Agricultural Productivity Gap Among Selected Countries*

YUJIRO HAYAMI

This study explores the causes of enormous agricultural productivity differences now existing among the developed and less developed countries. Factors are identified that determine the productivity gap, and their influences are gauged on the 1957–62 national aggregate data of 38 nations. Aggregate production functions are estimated on the cross-country data; and, with the estimates of production elasticities, the productivity differences between India and United States and between India and Japan are accounted for by conventional inputs (labor, land, fertilizer and machinery) and nonconventional inputs (education and research). The measured contributions of respective factors to the productivity differences provide a guideline for allocating development efforts in the less developed countries.

THIS essay aims to identify factors that determine differences in agricultural productivity of the developed and the less developed countries and to gauge the influence of these factors. Since Colin Clark [1] pioneered the work, those who have made international comparisons of agricultural production have been struck by the enormous gap in agricultural productivity existing in the world.[1] The gap is indeed great. Recent estimates by the author indicate that the gross farm output (net of seed and feed) per male worker of India is only 2.3 percent of that of the United States and 20.7 percent of Japan's for 1957-62 [6]. The exploration of this gap in agricultural productivity should now have priority, considering the fact that agriculture lagging at the low level of productivity constitutes a serious impediment to the industrialization and economic growth of developing nations today.

In this study, we shall identify factors that determine the farm output of nations by estimating the aggregate production function of world agriculture on the basis of cross-country data. With the estimates of production elasticities, we shall try to explain the differences in labor productivity in agriculture between the United States and India, and between Japan and India, by the factors identified.

The research on which this article is based started as part of a project at the Institute of Asian Economic Affairs in Tokyo and was completed at the University of Minnesota under the financial support of the Rockefeller Foundation. The author wishes to express his appreciation to all three institutions for providing opportunities to conduct the research. He also wishes to thank J. P. Houck, Kazushi Ohkawa, Chujiro Ozaki, W. L. Peterson, V. W. Ruttan, and Yasukichi Yasuba for suggestions and comments. Miss Kinuyo Inagi assisted with data collection and computation.

YUJIRO HAYAMI *is visiting associate professor of agricultural economics at the University of Minnesota, on leave from Tokyo Metropolitan University.*

Approach and Data

The basic approach used in this study consists of (1) estimating the aggregate agricultural production function of the unrestricted Cobb-Douglas form, using four separate variables for land, labor, fertilizer, and machinery, and introducing, in addition, variables for education and RDE (research, development and extension), on the basis of cross-country data of 38 nations,[2] and (2) accounting for the percentage differences in output per male worker between the United States and India, and between Japan and India, by the percentage differences in the conventional inputs per worker and in the levels of education and RDE (research, development, and extension) with the estimated production elasticities. Two categories of man-made factors, one a substitute for land and another for labor (A. K. Sen's landesque capital and laboresque capital [15]) are represented respectively by fertilizer and machinery. In principle, our approach is similar to the one adopted by Griliches to account for the "measured productivity growth" of U.S. agriculture with the production function estimated on the U.S. cross-regional data [4, 5].

Data were taken from the recent compilation of international agricultural production statistics prepared by the author, with associates, at the Institute of Asian Economic Affairs [6]. All variables for the estimation of production function are expressed as the aggregates of nations. In principle, flow variables are averaged for 1957-62 and stock variables are measured in 1960. Needless to say, availability and international comparability of data largely determined the specification of variables.

The output variable is the composite cross-country series of gross agricultural output, which is the geometric mean of three cross-country series of gross output net of seeds and feed. Each series corresponds to a set of farm-gate prices (or import prices) of the United States or Japan or India, used for aggregation. Output series with the set of prices of a nation are subject to the kind of bias characteristic of the Laspyres quantity index. By taking the geometric mean of three such series, we expected to cancel out the biases due to the special price structures of the respective nations.[3] Quantity data are mainly taken from FAO [17, 18, 19]. Due to

---

[1] The studies that followed Clark's pioneering work are surveyed in [2]. A more recent study is by FAO [20, pp. 95–134.]

[2] Nations included in the sample for the estimation of production function are Argentina, Austria, Australia, Belgium (including Luxemburg), Brazil, Canada, Ceylon, Chile, Taiwan Colombia, Denmark, Finland, France, Germany (Federal Republic), Greece, India, Ireland, Israel, Italy, Japan, Mauritius, Mexico, Netherlands, New Zealand, Norway, Peru, Philippines, South Africa, Spain, Surinam, Sweden, Switzerland, Syria, Turkey, United Arab Republic, United Kingdom, United States, and Venezuela. Major limitation for the size of sample is the availability of data, especially for seeds and feed [17].

[3] If we denote quantity produced of the jth commodity in the ith country by q_{ij}, corresponding quantity of seed and/or feed to be deducted by d_{ij} and the wheat relative prices of the

data limitations, capital formation and stock changes are not counted in the output, which may cause the underestimation of output for countries where livestock production or production based on perennial plants is expanding rapidly. Price data for the weights of aggregation are taken from various government publications.[4]

As the labor variable, we took the number of male workers in the economically active population in agricultural occupations (agriculture, fishery, forestry and hunting) of ILO [24], deducting the number of fishery and forestry workers. The deduction was made by multiplying the labor population in agricultural occupations with the ratios of the output of agriculture to the output of agriculture, forestry and fishery combined. The ratios were calculated on the set of Japanese price weights,[5] a convention adopted because of the data limitation. Their use must be causing bias to our labor series, but it is difficult to ascertain the direction of the possible bias. Only male workers are counted, in order to preserve international comparability. This may tend to underestimate labor for Asian countries.

The land variable is the area of agricultural land in hectares, including permanent meadows and pastures, as reported by FAO [19]. This specifi-

---

United States, Japan, and India, by $W(U)_j$, $W(J)_j$, and $W(I)_j$, respectively, our composite series of gross output, Y_i's, are expressed as

$$Y_i = \sqrt[3]{Y(U)_i \cdot Y(J)_i \cdot Y(I)_i}$$

where

$$Y(U)_i = \sum_j W(U)_j \cdot (q_{ij} - d_{ij}), \qquad Y(J)_i = \sum_j W(J)_i \cdot (q_{ij} - d_{ij})$$

and

$$Y(I)_i = \sum_j W(U)_j \cdot (q_{ij} - d_{ij}).$$

The underlying assumptions of the above aggregation procedures are: (1) there exist three types of relative price structures characteristic of the three stages of economic development, which may be called "Advanced Stage," "Mid-way Stage," and "Initial Stage;" (2) those three stages are represented by the United States, Japan, and India, respectively; and (3) bias arising from aggregating commodities by the prices of one of those representative countries will be cancelled out by taking the geometrical mean of three such series. Needless to say, it is arbitrary to assume the three stages (why not four?) and to represent the three stages by the United States, Japan, and India. It is the availability of data, rather than theory, that forced us to set the above assumptions. Readers can obtain more detailed information upon request to the author.

[4] The farm-gate prices of the United States are mainly taken from [27]; those of Japan, from unpublished data prepared for the estimation of farm output in Japan by the Research Division, Minister's Secretariat, Ministry of Agriculture and Forestry. The farm-gate prices of India are either taken from [9] or estimated from the wholesale and retail prices in [7, 8]. The import prices are calculated from [21].

[5] Quantity data for the output of fisheries in the tons of fish catches and in the numbers of whales caught are from [22] and those for the forestry output in the round-wood basis from [23]. Price weights are from [10, 11, 12].

cation of the land variable assigns equal weights to arable land and pasture land in the aggregation. In the course of analysis we will test the adequacy of this specification.

Fertilizer was measured as the sum of N, $P_2 O_5$, and k_2O in metric tons contained in commercial fertilizers consumed [19]. The only available data of international comparability for farm machinery were the total horse power of farm tractors.[6]

We prepared two sets of data for the levels of education: (1) literacy ratios and (2) school enrollment ratios for the first and second levels of education, adjusted for the different lengths of schooling in various countries. The former are the estimates by UNESCO for the mid-20th century [25, pp. 38-44]; the latter, averages of 1950, 1955, and 1960 figures from UNESCO [26]. By taking averages for the three years in five-year intervals, we tried to convert the school enrollment ratio, which is an indicator of increase in education, to the measure of stock of education. It is granted that neither the literacy ratio nor the school enrollment ratio is the direct measure of the levels of education of farm labor population. At best, they are rough proxies of "average education" per farm worker. There seems no *a priori* reason, however, to assume that those proxies move systematically apart from the movements in the average educational level of farm workers so as to cause serious bias in the estimate of education coefficients. As the measure of RDE, we took the 1958-62 averages of the numbers of graduates from agricultural faculties in the third level of education per 10,000 farm workers.[7] This is again a proxy. However, high correlation could be expected between this variable and the number of persons engaged in agricultural research, development and extension activities.

These data are all very crude. It would be extraneous to say more about nonconventional inputs. The inputs of conventional factors are measured in physical terms, and no value weighting was attempted in aggregation to adjust for heterogeneity in inputs. This could be especially crucial in the case of land. Also, no adjustments were made for the degrees of utilization of labor and machine. Given the crudeness of the observations, adequacy of the data specifications should be judged in terms of the results of analysis.

Ordinary least squares were applied to the estimaion of the Cobb-Douglas production function. Problems relating to the estimation of production function from cross-sectional data are well documented in Griliches [3, 5] and need not be repeated here. Because of the lack of data, we would largely be disclaimed for not testing alternative model specification and estimation techniques. In our case, it is likely that bias arising from specification error, if any, is more crucial than the one arising from the inappropriate choice of estimation technique.

---

[6] The data are given for OECD countries in [13]; for countries outside of OECD, the total horse powers of farm tractors are calculated from the numbers of farm tractors in [19] by assuming that the average H.P.'s of tractors and garden tractors are 30 and 5, respectively.

[7] Calculated from UNESCO [26].

Estimation of Production Function

The main results of the estimation of aggregate production function are summarized in Table 1. Considering the crudeness of the data, it is rather surprising that the estimated equations fit to the data so well and that the coefficients are as significant as they are. The coefficients remain fairly stable when education and RDE variables are added or subtracted, although the coefficients of land and machinery tend to move in opposite directions. The matrix of simple correlation coefficients among the variables is shown in Table 2. The intercorrelations among explanatory variables are not serious although, of course, the correlation between the educational variables, E_1 and E_2 is very high. It seems that we do not have to worry too much about the problem of multicolinearity.

The plausibility of the estimates in Table 1 can be judged in terms of the estimates of aggregate production function of various countries. Griliches' study [5] indicates that the production elasticities of U.S. agriculture range from 0.4 to 0.5 for labor, from 0.1 to 0.2 for land and fertilizer, from 0.1 to 0.3 for machinery, from 0.3 to 0.5 for education (or labor education) and from 0.04 to 0.07 for research and extension. On the whole, Griliches' estimates and those in this study coincide surprisingly well, despite the completely different sets of data used. Yuize has estimated the aggregate agricultural production function of Japanese agriculture for 1952-62 on cross-regional data [29]. His estimates of production elasticities of labor and land on a value-added basis are within the ranges of 0.4 to 0.6 and 0.2 to 0.4, respectively. Those estimates are consistent with the results of this study since the ratio of value added to gross output is around 0.7 in Japanese agriculture [12]. For the less developed countries we do not have the comparable estimates of aggregate agricultural production function. T. W. Schultz, however, has estimated the production elasticity of labor in Indian agriculture on the observations of influences of the 1918-19 influenza epidemic [14, pp. 58–70]. His estimate of labor's coefficient was 0.4, which is consistent with ours.

It is an interesting finding of Griliches that in U.S. agriculture percentage increase in education, which improves the quality of labor, has the same output effect as percentage increase in labor itself [3, 5]. In order to test whether the same assertion holds in international dimension, we have estimated the production function by combining labor and education variables in a multiplicative form. Combining the variables brought little change. Furthermore, analysis of variance by using F-statistics provided evidences in support of the equality in the coefficients of labor and education.[8]

Sums of the estimated coefficients of conventional factors are not significantly different from one. We cannot discuss internal scale economies (scale economies at farm firm level), as Griliches did for the U.S. agriculture [5], because our data are national aggregates but not measured at per-farm basis. All we can infer is that constant returns prevail at national aggregate levels. This might, however, be one of the distinctive characteristics of agricultural production compared with industrial production and, if so, would have important implication on inter-sectoral investment priority for national economic development.

Theoretically, the regression estimates of economic relations on cross-country data are those of long-run equilibrium. This seems to justify the choice of agricultural land (simple sum of arable land and permanent pasture land) as land variable. It is, however, questionable if this choice of land variable is really adequate. There have been attempts to convert uncultivated pasture land to arable land equivalent with weights more or less arbitrarily chosen [16, p. 154; 28, pp. 7–8]. In this study we tried to estimate the weight in the regression analysis. For the estimation of Regression 1, we defined the land variable as $(A + kS)$, where A, S, and k are respectively arable land area, pasture land area, and the weight to be placed on the latter; and we ran the regression changing k parametrically from 0 to 1. The result was that k converged to 1 with the highest coefficient of determination.[9] A possible interpretation is that the proportion of arable land area to the area of permanent meadows and pastures is a variable determined through adjustments in the method of farming to the demand for agricultural land, and that the production relations estimated on cross-country data are those reached when the adjustments are completed. Economic factors, not climatic, are the dominant factors in determining the intensity of agricultural land use. This is a bold hypothesis, and the present test of it is not yet conclusive. It should be worthwhile to explore this problem in the future.

---

[8] The F-statistics calculated for testing the null hypothesis of equality in the coefficients of labor and education are 0.55 for Regression 2 *vs.* Regression 4, 0.03 for Regression 3 *vs.* Regression 5, 0.18 for Regression 6 *vs.* Regression 8 and 0.05 for Regression 7 *vs.* Regression 9.

[9] The coefficients of determination (unadjusted) for various k's are as follows:

k	0	0.05	0.1	0.2	0.3	0.4
R^2	0.9331	0.9368	0.9392	0.9417	0.9430	0.9438
k	0.5	0.6	0.7	0.8	0.9	1.0
R^2	0.9442	0.9445	0.9447	0.9448	0.9449	0.9450

[b] E_1 and E_2 are respectively literacy ratio and adjusted school enrollment ratio.

[c] Sum of coefficients of F, M, T and L (or $L \times E_1$ or $L \times E_2$).

Accounting for the Productivity Gap

On the basis of the production elasticities of various factors estimated in Table 1, we will attempt to account for differences in agricultural output per male worker between the advanced and the less advanced countries. We will compare the United States and India as they represent the two categories of countries. Also, we will compare Japan and India as

Coefficients of \ Regression number		6	7	8	9
Fertilizer	F	0.133 (0.061)	0.158 (0.063)	0.126 (0.058)	0.154 (0.059)
Machinery	M	0.064 (0.061)	0.100 (0.060)	0.053 (0.053)	0.097 (0.057)
Land	T	0.241 (0.053)	0.229 (0.055)	0.248 (0.050)	0.232 (0.054)
Labor	L	0.527 (0.077)	0.482 (0.077)		
Education[b]	E_1	0.460 (0.198)			
	E_2		0.429 (0.278)		
$L \times E_1$				0.538 (0.072)	
$L \times E_2$					0.489 (0.070)
RDE	U	0.109 (0.063)	0.060 (0.062)	0.114 (0.061)	0.059 (0.060)
Constant term		0.286	0.386	0.130	0.268
$\bar{R}^2$		0.954	0.950	0.955	0.952
S.E.		0.1348	0.1408	0.1331	0.1387
Sum of coefficients[c]		0.965 (0.036)	0.969 (0.039)	0.965 (0.036)	0.972 (0.038)

they are more comparable in such conditions as population density and the type of farming.

Differences in output and inputs per worker and in the levels of education and research between the United States and India, and between Japan and India, are measured in percentage terms in Table 3 (last two columns). In order to account for the measured productivity gaps, the following set of production elasticities was adopted with reference to Table 1: 0.45 for labor, 0.20 for land, 0.20 for fertilizer, 0.15 for machinery, 0.45 for education, and 0.10 for RDE. Based on the statistical evidence in

Table 2. Matrix of simple correlation coefficients among variables (in logarithms) used for the estimation of production function in Table 1

		Y	T	L	F	M	E_1	E_2	U

Machinery (HP per worker)	M/L	45.9	1.07	0.0077	100.0	99.3
Agricultural land (Ha. per worker)	T/L	129.7	1.43	1.99	98.5	−39.2
Education (percent)	E_1	97	98	18	81.4	81.6
	E_2	101	90	26	74.3	71.1
RDE (graduates per 10 thousand workers)	U	22.8	14.2	0.40	98.2	97.2

[a] Data are from [6].

Table 1, the elasticities of conventional variables are so selected as to add up to unity.

Since our production function is now presumed linear homogeneous in Cobb-Douglas form, we can assume the following approximation formula:

$$\left(\frac{\dot{Y}}{L}\right) = 0.20\left(\frac{\dot{T}}{L}\right) + 0.20\left(\frac{\dot{F}}{L}\right) + 0.15\left(\frac{\dot{M}}{L}\right) + 0.45\dot{E} + 0.10\dot{U} + e$$

where the figures with dots are the percentage differences in output and conventional inputs per worker and in nonconventional inputs (see notations in Table 3) of any two countries, and e is residual. The residual term includes the error due to approximation in addition to the errors involved in the estimation of parameters. Each term in the righthand side of the above equation represents the contribution of each factor to the percentage difference in labor productivity in agriculture. The results of applying the above accounting formula to the percentage differences in output and inputs in the last two columns of Table 3 are summarized in Table 4. Two cases are tried, one using literary rate for educational variable ($E=E_1$); the other, school enrollment ratio ($E=E_2$). The numbers in parentheses measure the relative contributions of respective factors, assuming the percentage difference in labor productivity (the Y/L entry in the last two columns of Table 3) is 100.

Table 4. Contributions of various factors to the international differences in farm output per male worker in percents[a]

Contributions of		United States vs. India		Japan vs. India	
		$E = E_1$	$E = E_2$	$E = E_1$	$E = E_2$
Fertilizer	0.20 $\dot{F}/L)$	20.0 (21)	20.0 (21)	19.8 (25)	19.8 (25)
Machinery	0.15 $(\dot{M}/L)$	15.0 (15)	15.0 (15)	14.9 (19)	14.9 (19)

RDE	0.10 $\dot{U}$	9.8 (10)	9.8 (10)	9.7 (12)	9.7 (12)
Residual	e	−3.4 (−4)	−0.2 (0)	6.0 (7)	10.7 (14)
Sum of conventional factors[b]		54.7 (56)	54.7 (56)	26.9 (34)	26.9 (34)
Sum of non-conventional factors[c]		46.4 (48)	43.2 (44)	46.4 (59)	41.7 (52)
Productivity difference $(\dot{Y}/L)$		97.7 (100)	97.7 (100)	79.3 (100)	79.3 (100)

[a] Differences in inputs and output per worker between India and the United States or between India and Japan are measured in percent, with the United States or Japan used for the base: Denoting India by 1 and the United States or Japan by 0, the difference in a variable X is measured as $\dot{X}=(x_0-x_1)/x_0\times 100$. Relative contributions with $(\dot{Y}/L)=100$ are given in parentheses.

[b] $0.20\ (\dot{F}/L)+0.15\ (\dot{M}/L)+0.20\ (\dot{T}/L)$.

[c] $0.45\ \dot{E}+0.10\ \dot{U}$.

Conspicuous difference in the endowment of land relative to labor explains only 20 percent of the productivity gap between the United States and India. Difference in the use of fertilizer accounts for an equal percentage in this productivity gap. Much greater is the influence of education. Education and RDE together explain almost half of the difference in agricultural productivity between the United States and India. The importance of education is more pronounced when Japan is compared with India. Education's contribution to the gap in agricultural productivity between Japan and India amounts to 40 percent, and, together with RDE, amounts to more than 50 percent. The present study indicates India can double her agricultural production only by improving education to its present level in Japan.

Conclusion

In this study, by estimating aggregate agricultural production function on cross-country data, factors have been identified that could influence the level of farm output. With the estimates of production elasticities, the major portion of the enormous difference in the labor productivity of agriculture between the advanced and the less advanced countries has been explained by the factors identified. It was found (1) that differences in the inputs of modern man-made factors account more for the difference in productivity than differences in the endowments of original factors and (2) that education and research are crucial in determining the productivity gap. These findings are consistent with the Schultzian hypothesis that the strategic factors for the transformation of low productive traditional agriculture to highly productive modern agriculture are the new profitable inputs such as chemical fertilizer and the improved varieties of seeds.

We should be cautious, however, in deriving any policy implication from the results of this study. In addition to the problems involved in data and estimation procedures, the present approach has an intrinsic weakness in that the influence of complementarity among factors can not be evaluated. The complementarity could be of particular importance between conventional and nonconventional factors. Improvement in seeds is not effective unless accompanied by increase in the application of fertilizer. Most labor-saving innovations do not materialize without investment in new machinery. The measured contributions of education and research indicate that increases in those nonconventional inputs are required for the less developed countries to close the agricultural productivity gap. But the investment in education and research alone may not bring the measured contribution to output unless it is accompanied by increases in complementary conventional inputs. We can infer that the less developed country can not close the existing productivity gap without investing in education and research to improve the quality of labor and to create better techniques suited for their local environments, but such investment might not be fruitful unless complemented by the efforts to improve the conditions of supply of modern conventional inputs such as fertilizer and machinery. In order to draw a more reliable policy guideline for allocating development efforts, it is necessary to exploit the present approach by improving data and estimation techniques, and, at the same time, to develop an alternative approach that will make it possible to evaluate the complementarity among the production factors.

A Simulation Study of Population, Education, and Income Growth in Uganda[*]

PHILLIPS FOSTER AND LARRY YOST

Increases in educational level tend to increase income. Higher community income in turn can enable more resources to be put into education. However, increases in population tend to spread scarce educational resources over more children, thereby inhibiting the rise in level of living that can come through increasing the educational investment in each individual. This paper analyzes for a developing economy how changes in birth and death rates affect population growth and educational and economic development. A simulation model of these demographic, educational, and economic processes, based on empirical data from the Buganda tribe in Uganda, is used to study the extent and timing of the responses. Both the method and the empirical results should have relevance for readers concerned with growth and development.

THIS STUDY attempts to clarify the relationship between population growth, expenditure on education, and economic development in an underdeveloped rural economy.

The problem was to estimate, through simulating the growth of a micro-socio-economic system a number of times, the probable impact of differential rates of population growth on the rate of growth of per capita income in a rural community in Uganda. We began with the hypothesis that over an extended period of time, such as 30 years, an inverse relationship exists between the rate of growth of rural population and the rate of growth of its per capita income. Implicit in this hypothesis was the assumption that formal education would play a crucial role in the relationship, should it exist.

A model was developed containing the economic relationships thought to be relevant to the problem. The economic model then became the basis for an econometric model which was used in simulating the behavior of the economy through time. The basic logic of the economic model used in this study borrows heavily from work by Coale and Hoover [1]. The method of simulating the growth of a population through time was suggested by Orcutt [4]. What is methodologically new in this study is the grafting of an economic model of a peasant economy to the population

simulation technique developed by Orcutt et al. The econometric model that resulted from this fusion uses a combination of the Markov Chain[1] and Monte Carlo techniques.

General View of the Model Used

The model used in this study, diagrammed in Figure 1, has three decision-making components: demographic, educational, and income, each consisting of a set of three decision-making units—individuals, families, the community. Each unit can vary from year to year as status variables, and each participates in the operation of the model in combination with one or more sets of probabilities or functional relationships. As the decision-making components operate and interact through time, they produce outputs that in turn influence the operation and interaction of the decision-making components.

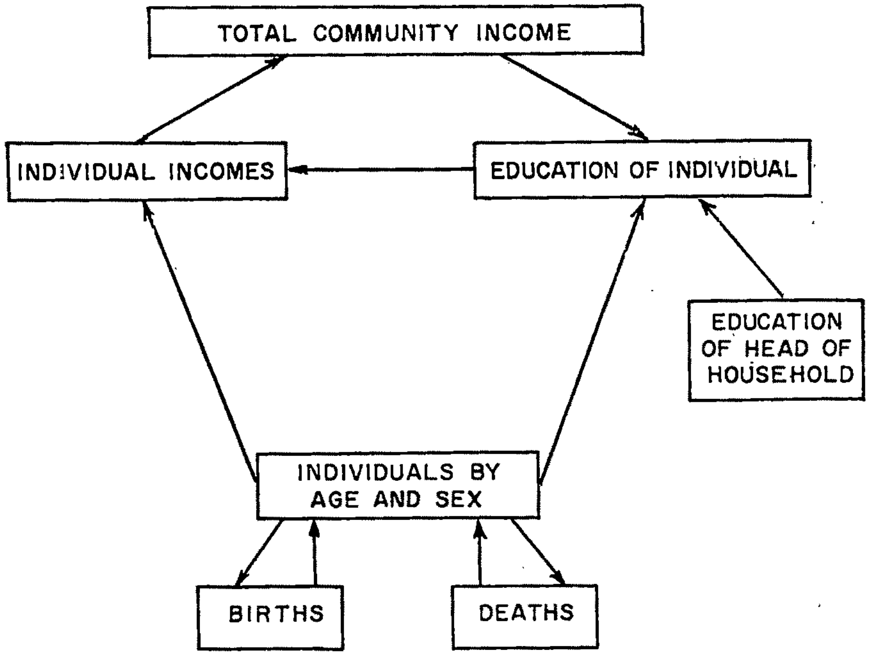

Figure 1. Basic economic model

The demographic decision-making component contains individuals whose status varies by age, sex, marital status, and, for females, the time interval since the last child was born. Changes in age and sex take place each year as births and deaths occur. Birth rates are a function of both the age and sex structure of the population and of the age specific fertility rates[2] of the community. Given a set of birth probabilities, the number of births changes as the age and sex composition of the population changes. Likewise, the number of deaths is dependent upon the age and sex makeup of the population, given a fixed set of death probabilities.

---

[1] Individuals in the study community have certain probabilities of moving from one set to another from year to year, within certain constraints.

The educational decision-making component uses all three decision-making units. An individual's educational level is a function of his age and sex, the education of the head of household,[3] and the total community income. The amount of money available for education, which is dependent upon the total community income, is a key constraint on the level of education. Generally, the greater the amount of money available for education, the higher is the level of education attainable in the community, and vice versa.

The income decision-making component of the model is built up from individual income and total community income. An individual's income depends on his education, age, and sex, while total community income is the sum of the individual incomes.

It is the complexity of the interactions among the components of this model through time that makes the simulation technique used appropriate to testing the hypothesis that is the focus of this paper. These interactions generated three major outputs: (1) population structure of the selected community for each year over a 30-year period; (2) annual educational achievement in the community within the estimated demographic, income, and other constraints; and (3) annual incomes in the community, given the estimated demographic, educational, and other constraints.

Each output is affected by the three decision-making units, whose characteristics vary from year to year. Those varying characteristics necessary to our econometric model are called status variables. The year-to-year operation of the model is affected by its annual outputs, such as births, deaths, marriages, etc. The decision-making units and status variables, as well as types of probabilities, functional relationships, and annual outputs used in our model as they are related to the decision-making components, are listed in Figure 2.

The Study Community

Kako community of the Buganda tribe in Uganda was selected for this study. The area, known informally as Kako Hill [2], is located about

---

[2] The age specific fertility rate is the total number of live births per 1,000 female population of a given age cohort. This rate can be converted to the age specific birth probability by dividing it by 1,000.

[3] The educational level of the head of any household is not an independent variable, as Figure 1 suggests, but actually depends on other variables that in the past have influenced the education of the individual. These relationships are not indicated in Figure 1, however, in order to keep the diagram relatively simple.

Decision-making component	Decision-making unit	Status variables	Examples of probabilities and/or functional relationships	Examples of annual outputs
Income	Individual	Age Sex Marital status Educational level Income	Income step production function	Individual income
	Community	Population		
Demographic	Individual	Age Sex Marital status Interval since last child	Marriage rules and constraints Sexing probabilities	Births Deaths Family formation
	Community	Age specific birth rates Age specific death rates	Age specific birth probabilities Age specific death probabilities	
Education	Individual	Age Sex Educational level	Starting-school index Staying-in-school index	School entrants School leavers
	Family	Education of head of household		
	Community	Total income Proportion of community income spent on education		Amount spent on education

Figure 2. **Decision-making units, status variables, probabilities, functional relationships, and annual outputs as related to decision-making components**

seven miles northeast of Masaka and 70 miles southwest of Kampala, the capital of Uganda. In 1965, at the time of the field work, 1,677 persons in 423 households lived there, a base population small enough to allow a complete census of the current relevant decision-making units, status variables, and outputs, as shown in Figure 2.

Agriculture provides the economic base for Kako Hill. When the census for this study was taken, over 95 percent of its households were growing at least a few crops, and fewer than one-tenth of the working population worked off the farm. In addition, many of the off-farm occupations were closely related to agriculture. To some extent, the community was an economic enclave, with an estimated per capita income in 1965 of 596 shillings, or $84 [3].

Kako Hill has four schools (one has only grade 1; two have grades 1–8; and one, grades 9–12), with five additional schools (all offering grades 1–6) near its boundary. Residents can send their children through high school without sending them away to boarding school. At the time of our field work, over half the school-age population was in school and 18 percent of the income of the community was being spent on educating its children. The possible age range for the school population was 4 through 29 years; however, the oldest person who actually was in school at the time of the census, or who was simulated to be in school by the model, was a 25 year old person who was in graduate school in India in 1965.

In 1965, Kako's birth rate was 38.5 per thousand people; its death rate, 21.5 per thousand; its population growth rate, 1.7 percent per year.

Decision-Making Components of the Model

As previously indicated, there are three major groups of decision-making components in the model: demographic, income, and educational.

Demographic component

The demographic decision-making component includes death probabilities, birth probabilities, sex probabilities for new babies, selection of women of child-bearing age, and the marriage function.

Sex and age specific death probability tables were prepared for the community from survey data, supplemented by data from the two most recent government censuses. The data in these tables showed the probability of death or of having a baby for persons in 24 age-sex categories.

During the simulation, when an individual was brought into the system for processing, his death probability was selected from the table of death probabilities depending on his age and sex. A random number generator then provided a number between zero and one. If the number was equal to or less than his death probability, he did not die, but was passed on through the other operations of the system.

The birth probabilities furnished the decision-making components that determined when a woman of child-bearing age gave birth. The associated status variables were the woman's age and years since she had her last child. The birth probabilities were calculated as follows:

$$\frac{B_{ij}}{W_{ij}} = P_{ij}$$

where

B_{ij} is the number of women in age category i (i = 10–14, 15–19, 20–24, 25–29, 30–34, 35–39, and 40–50) and years since last child category j (j = 0–2, 3–5, and over 5) who gave birth to a child in 1965;

W_{ij} is the total number of women in age category i and years since last child category j in the population in 1965; and

P_{ij} is the probability that a woman in age category i and years since last child category j will give birth to a child.

The probabilities thus generated were used in the simulation to determine whether a woman gave birth to a child during the year under consideration. The procedure was similar to that used for the "death determination" described earlier.

The sex of each new baby was determined by the use of a sexing probability in combination with the random number generator.

The marriage function required that both the man and the woman be single before either could be considered for marriage and that the man be between 3 years younger and 12 years older than the marriageable woman. This was consistent with the marriage age customs observed during the field work.

Income component

The step production function for income for males not in school is shown in Table 1. Other income production functions were calculated for females not in school, and for males and females in school. The method for estimating farm and off-farm income and for allocating income among individuals is discussed elsewhere [3, p. 11–28]. In the simulation, any individual ten years old or older was processed through the labor force operation. An income was selected for him from one of the income production function tables based on his age, sex, education level, and whether or not he was in school. This income figure was then added to the sum of the incomes of all individuals who had already gone through the labor force operation during that year's run. When every member of the population had been passed through the system that year, the total community income was calculated.

Table 1. Annual incomes for males not in school[a]

Years of schooling of individual	Age of individual					
	10–14	15–19	20–29	30–44	45–65	66 and over
0	114	373	464	558	554	397
1–4	229	628	870	696	527	723
5–8	220	879	1,049	1,728	2,312	1,361
9–12	294[b]	1,417[b]	3,687	2,920	10,107	6,893[b]
13 and over	—	14,486[b]	27,000	15,600	25,600	15,000

[a] Incomes are stated in East African shillings.
[b] Calculated by interpolation or extrapolation.

Educational component

If an individual was between the ages of four and ten and had not yet dropped out of school, a starting-school index number was calculated for him. This index was developed from our survey data and was based on the child's age and the years of schooling of the head of his household. Field data indicated that sex does not seem to influence starting-school probabilities.

The index was calculated as follows:

$$\frac{R_{ij}}{R_{ij} + N_{ij}} = P_{ij}$$

where

R_{ij} is the number of individuals age i ($i = 4, 5, \ldots 10$) who entered school in 1965 and whose heads of households had j ($j = 0$, 1–4, 5–12, and over 12) years of education,

N_{ij} is the number of individuals in the population age i who were not in school in 1965 and whose heads of households had j years of education,

P_{ij} is the index for a possible school entrant age i and whose head of household had j years of schooling.

A staying-in-school index was also calculated, based on field observations relating the student's age and sex and the years of education of his household head. Sex was included as a relevant factor in this index because in Uganda, a girl who reaches senior secondary school is much less likely to remain in school than a boy of the same age with similar family characteristics.

The staying-in-school index was calculated as follows:

$$\frac{R_{ij}^k}{R_{ij}^k + N_{ij}^k} = P_{ij}^k$$

where

R_{ij}^k is the number of individuals sex k (k=male, female,) and age i (i =5–7, 8–10, 11–12, 13–14, 15–16, and over 16), whose heads of household had j (j=0, 1–4, 5–12, and over 12) years of schooling and who were in school in 1965,

N_{ij}^k is the number of individuals sex k, age i, and whose heads of household had j years of schooling who were not in school in 1965,

P_{ij}^k is the index for an individual having the possibility of remaining in school of sex k, age i, and whose head of household had j years of schooling.

During the simulation, when an individual who met the criteria for starting or staying in school came into the system, a starting-school or staying-in-school index was calculated for him. When all individuals in the population had entered the system for that year and those who met the starting-school or staying-in-school criteria had been assigned an index, they were arrayed from the individual with the highest index to the one with the lowest. Individuals were then picked from this array, one at a time, from the highest downward, until the cumulative cost of education for the individuals equalled the amount of money available for education that year. The rest of the individuals in this array either did not enter school that year (if they were potential entrants) or were dropped out of school (if they had been in school last year).

The school costs function was made up of the cost estimates for educating a student for one year in each of grades 1–21.[4] It was assumed that a few students would go on to college, some even to graduate school or professional school, and that much of their support at those levels would come from the local community in which they were brought up.

The money available for education in any year of the simulation was calculated by multiplying the total community income of the previous year by 18 percent, the proportion of community income spent annually for education.

Population Expansion Patterns

Five alternative population expansion patterns were produced by making arbitrary changes in the birth and death probabilities. The first pattern was the result of using birth and death probabilities obtained from the field survey. The simulation production run using these probabilities had an average annual population growth rate of 2.3 percent. (This run was therefore labelled run 2.3; other runs were labelled similarly.) This average population growth rate during the 30-year simulation was higher than the growth rate at the time of the field work because of the relatively large number of females then about to move into the childbearing years (Figure 3). The age structure of the population when our simulation was begun suggests that rate of population growth spurted upwards about 15 years earlier. This could have been due as much to a drop in the infant mortality rate as to an increase in the fertility rates; whatever its cause, the demographic impact of the resulting broadly based population pyramid is evident in each of the simulation runs.[5]

In the second simulation, the death probabilities were arbitrarily lowered enough to reduce the 1965 crude death rate ten points (from 21.5 to

---

[4] There were actually 12 grades in the primary through senior secondary school levels. Higher school, college, technical school, and graduate school were considered in the study on the basis of the number of years of school beyond the twelfth grade. Since it was assumed that anyone going on to college and graduate school could finish a Ph.D. or M.D. degree in 9 years or less, 21 years or grades of schooling were assumed possible in the simulation.

[5] The age specific fertility rates for the 20–29 year old females were understandably much higher than for the other age ranges. This, plus the relatively large number of females between 0 and 14 years of age when the simulation began, caused the crude birth rate in the census year to be lower than it would have been for a more "normal" female age distribution with the same set of fertility rates. Therefore, after each simulation had progressed about six years, the relatively large number of females who were in the 0–14 age range during the survey year began moving into the 20–29 age range. The movement of a large number of women into this high birth probability range caused the birth rate to increase. With the death rate fluctuating relatively less than the birth rate, the population growth rate of each simulation began a noticeable increase after the first six years or so of simulation. After some 20 years, the original 0–14 year old cohort of females had moved through or into the 20 to 29 year range and population growth rates started to level off or recede.

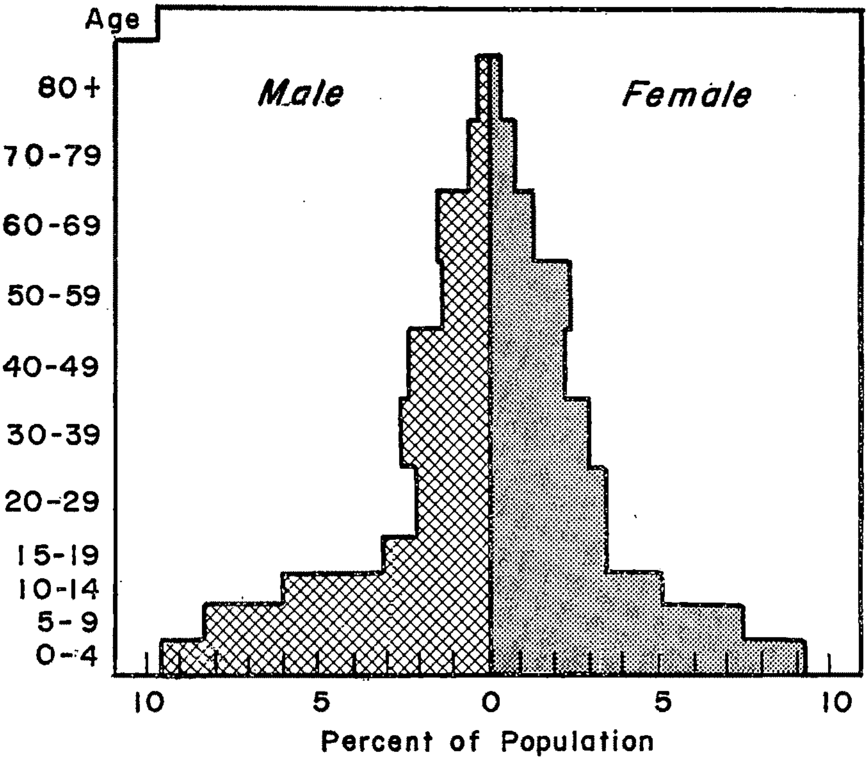

Figure 3. Age-sex pyramid at the start of each simulation

11.5 per thousand).[6] This production run yielded an average annual population growth rate of 2.7 percent.

For the third simulation, the age specific fertility probabilities were arbitrarily lowered enough to reduce the 1965 crude birth rate 10 points (from 38.5 to 28.5 per thousand) and the death probabilities were held at the same level as in the first run. The average annual population growth rate during this 30-year run was 2.1 percent.

The fourth simulation was made using birth and death probabilities associated with base year birth and death rates of 18.5 and 11.5 per thousand, respectively; that is, the 1965 crude birth rate was lowered 20 points and the crude death rate 10 points. This run was to show the simulation output results when population was growing at a low rate. The average population growth rate resulting from this run was 1.2 percent. It should be noted that, although this was the slowest population growth rate of all the simulations, it is still faster than the present population growth rates of Europe and the United States.

---

[6] With improvement in nutrition, medical facilities, and sanitation, it is probable that the Kako crude death rate will be reduced to somewhere between 10 and 15 per thousand during the next few years.

For the final simulation, fertility probabilities were increased to yield a 1965 birth rate of 51.5, and death probabilities were adjusted to yield a 1965 death rate of 11.5. These changes were made in order to give a set of birth and death probabilities that would yield a high population growth rate. This run produced a 3.7 percent annual growth rate.

These five runs provided results within a farly wide range of realistic annual population growth rates, from 1.2 to 3.7 percent.

Results of the Simulations

The simulation technique used investigates the relationship between income growth and population growth derived from the following feedback loop: Educational level, age, and sex determine an individual's income and hence the total income of the whole group of individuals; the total community's income is allocated in a fixed proportion to producing educational services for the school age population; the amount of education provided the school age population heavily influences its income after it leaves school. The loop is thus closed. With a different set of birth and death probabilities assigned to each production run, the differential results obtained are attributable to the different ways the population grew.

Total population at the beginning of each simulation was 1,677. At the end of the five simulations, it ranged from a low of 2,379 to a high of 4,632 (Figure 4).

The dependency ratio (proportion of population under 15 years of age) of the five runs varied from 31 percent at the end of 30 years for run 1.2 to 53 percent for run 3.7 (Figure 5). At the end of the sixteenth year the spread was even greater—24 percent versus 52 percent.

All the dependency ratios, except the one associated with the fastest rate of growth of population, experienced a general depression centering roughly on year 15 of the simulation. As explained above, this occurred because the population pyramid with which the simulation began had an especially broad base. Our simulation suddenly stabilized the age specific fertility rates and the result, among the slower growing population simulation runs, was a tendency for the dependency ratio to fall as the "over-sized" younger cohorts moved into older cohort status. Then as these same "over-sized" cohort groups moved into the most fertile child bearing age, they sent the birth rate back up and the dependency ratio thus began moving up again. This phenomenon is depicted clearly in Figure 6, especially in run 1.2 and run 2.1.

The average years of schooling of the community population over the 30 years continually increased for all five runs (Figure 7), but the rate of increase differed. At the end of the 30-year period, the average level

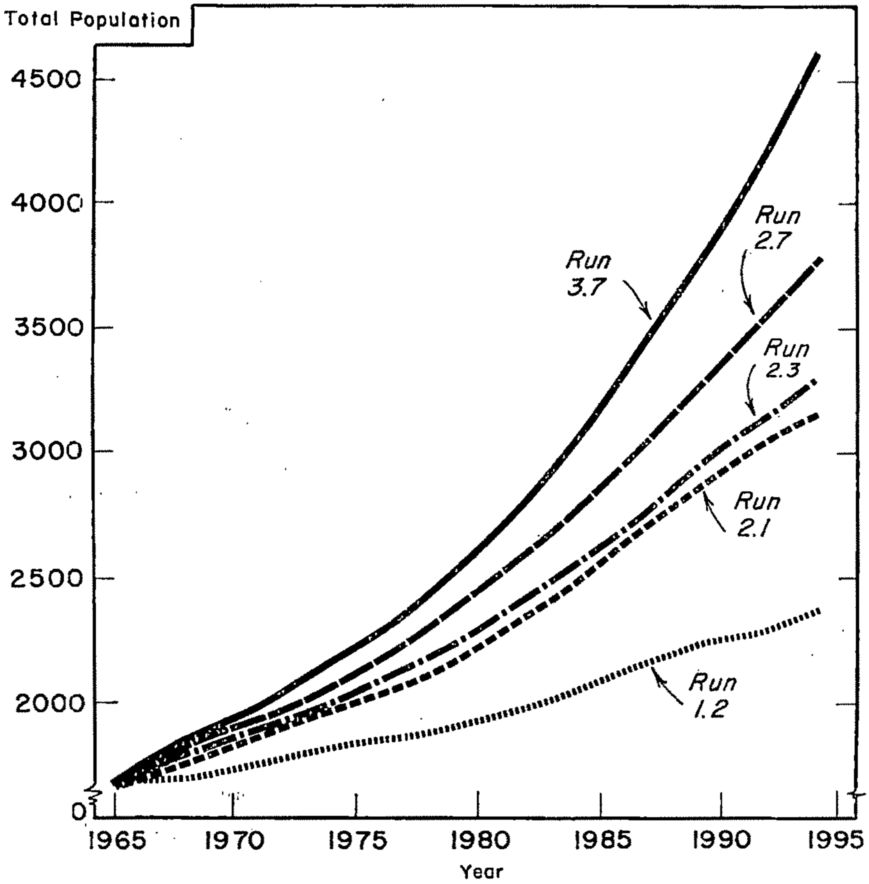

Figure 4. Total population annually for each simulation

of education ranged from a low 5 years for run 3.7 to a high of over 7 years for run 1.2. Using this data, an equation was fitted by least squares. The resulting equation was $y = 4.75 - .50x$; ($R^2 = .93$), where

y is the annual percentage increase in average educational level,[7]

---

[7] Annual percentage increase in average education level was calculated by the formula

$$PL = FL/(1 + r)n$$

where

PL = present average educational level,
FL = average education level in year n ($n = 30$),
r = annual percentage increase in average education level, and
n = number of years over which the calculation is made, i.e., years between PL and FL.

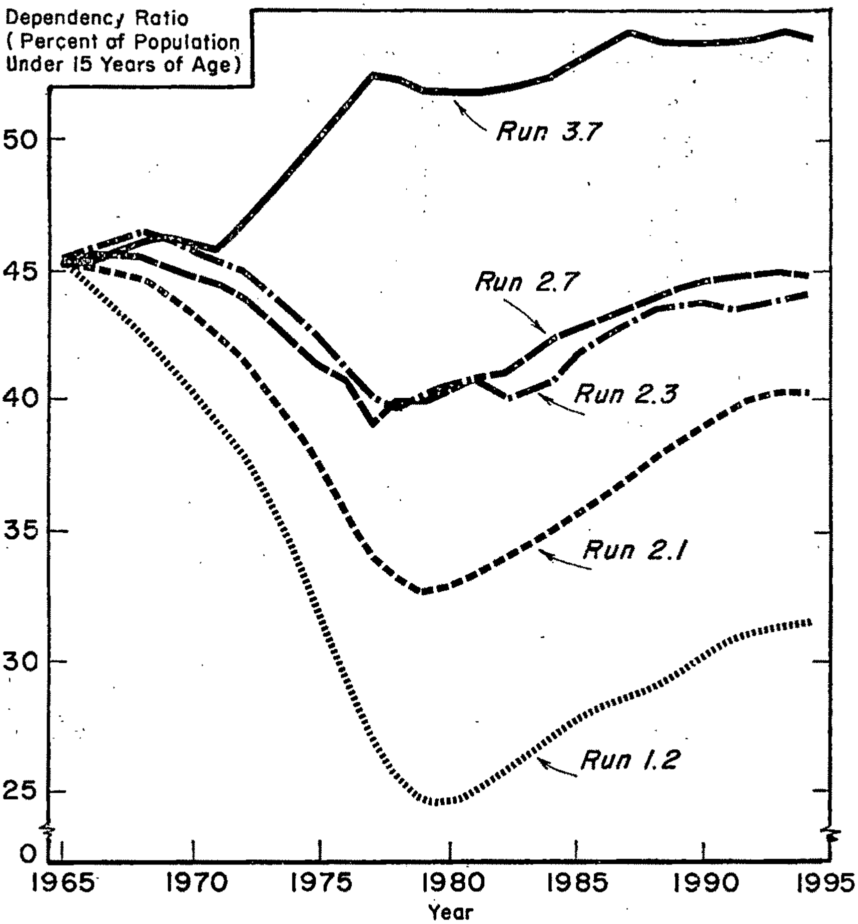

Figure 5. Dependency ratio annually for each simulation

and

x is the population growth rate.

The per capita income increased during each of the five simulations (Figure 8). At the end of the 30 years, it ranged from a low in run 3.7 of 1,429 shillings to a high in run 1.2 of 2,972 shillings.

The percentage increases in annual per capita income (rate of economic development) varied from a low of 3.04 percent (run 3.7) to a high of 5.56 percent (run 1.2). Runs 2.1, 2.3, and 2.7 had increases in annual per capita incomes of 4.93 percent, 4.84 percent, and 4.85 percent respectively.[8]

---

[8] These figures were calculated by use of the formula

$$PI = FP/(1+r)n$$

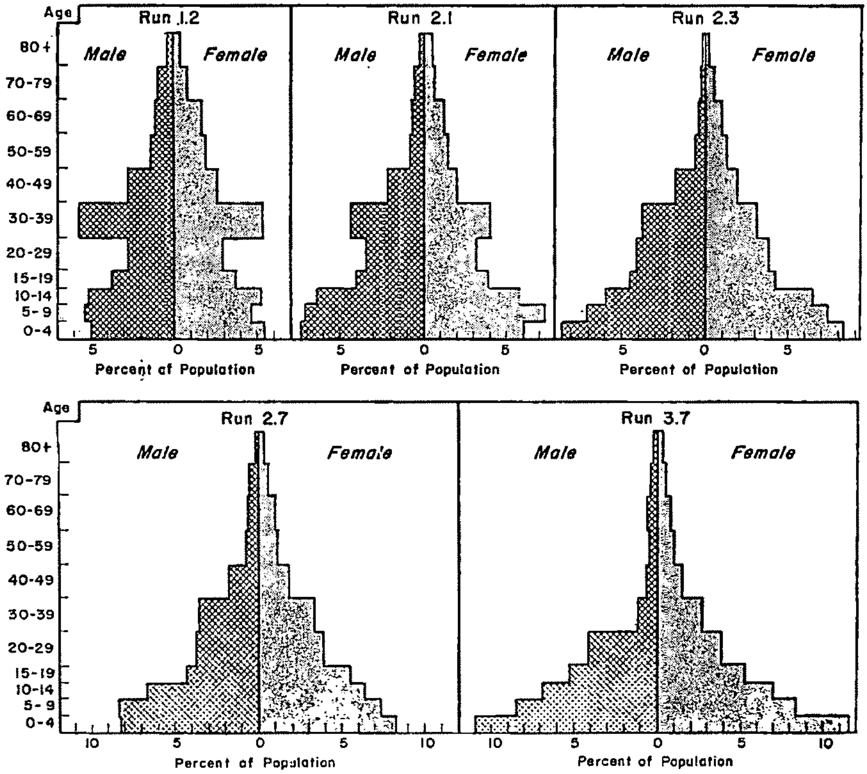

Figure 6. Age-sex pyramid at the end of each simulation

To these results, a function was fitted by least squares. The resulting equation was $y = 6.42 - .98x$; ($R^2 = .88$), where

y is the annual percentage increase in per capita income,

and

x is the population growth rate.

This equation summarizes the most important finding of our study. It suggests that in Kako community in Uganda, over a 30-year period, a reduction in the rate of growth of population from, say, 3 percent annually to 2 percent will, in and of itself, increase the annual rate of growth of per capita income from 4.0 percent to 4.98 percent. Conversely, an increase in rate of growth of population from 2 percent annually to 3 per-

---

where

PI = per capita income in year one,
FP = per capita income in year n ($n = 30$),
r = percentage increase in annual per capita income, and
n = the number of years over which the calculation was made.

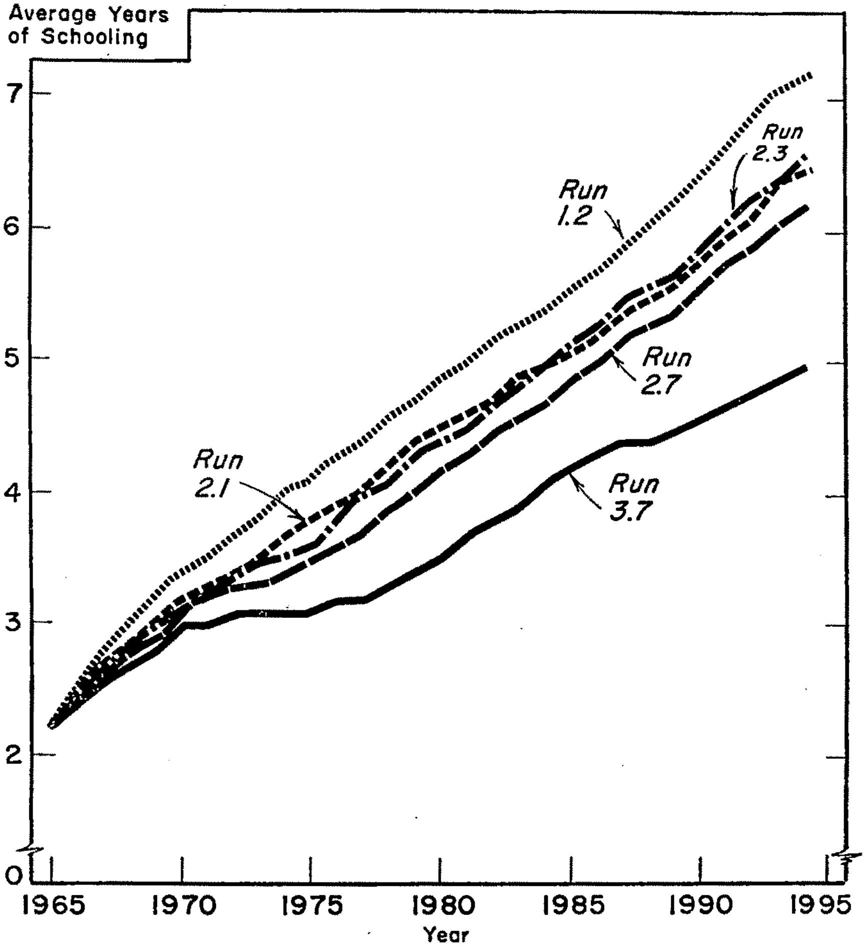

Figure 7. Average years of schooling annually for each simulation

cent annually will result in a decrease in rate of growth of per capita income from 4.98 to 4.0 percent.

Put less precisely, but perhaps more understandably, this equation suggests that, for each percentage point or fraction of a percentage point development planners can reduce the rate of growth of population in this community, they can expect an approximately equal increase in rate of growth of per capita income. Conversely, for each percentage point or fraction of a percentage point development planners allow the rate of growth of population to increase in this community, they can expect an approximately equal decrease in rate of growth of per capita income.

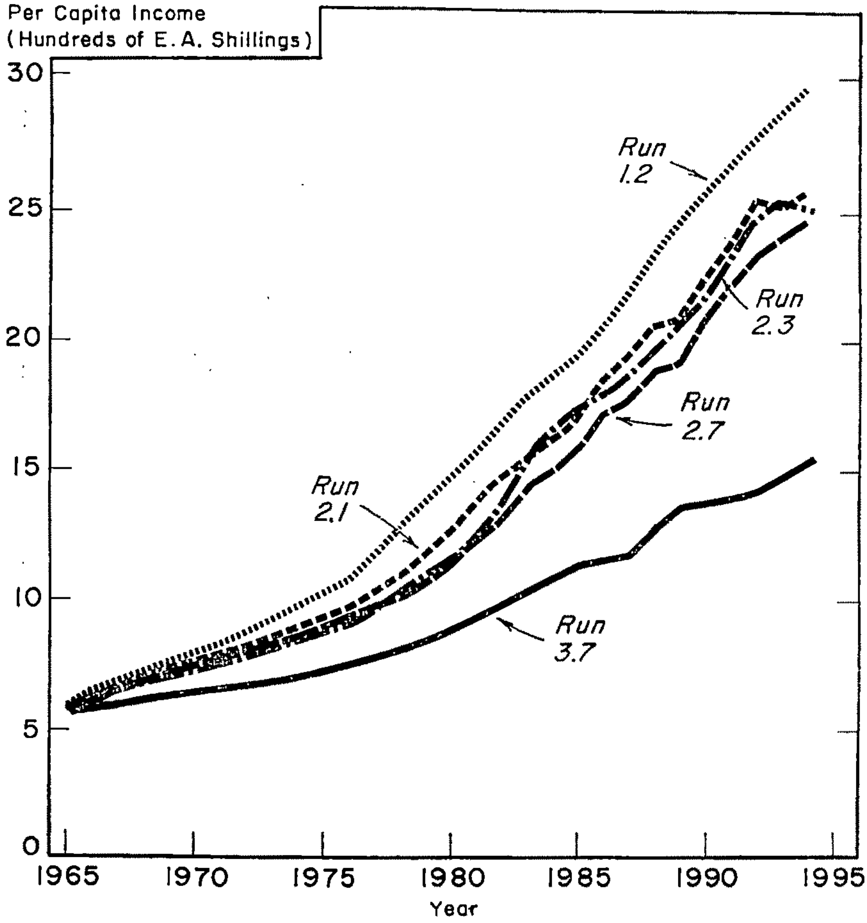

Figure 8. Per capita income annually for each simulation

Summary and Implications

Through time in Kako community in Uganda, a marked inverse relationship apparently exists between population growth rate and rate of increase in per capita income. This relationship seems to be closely associated with the inverse relationship, suggested by our simulation results, between population growth rate and the capacity of Kako community to educate its children. A high population growth rate in this community will probably be seriously deterimental to economic development, its dampening effect increasing in degree as the population growth rate increases.

The econometric model we developed to simulate our economic model through time could be used for a country or regional population on a sample basis. The results from such simulations could have even greater value to economic development planners than our present study. Furthermore, our econometric model can be altered for a number of different research interests and may thus have many possibilities for further use.

"Disguised" Unemployment Once Again: East Pakistan, 1951–1961*

WARREN C. ROBINSON

The concept of "disguised" unemployment plays an important role in development theorizing, yet its empirical content is uncertain. This paper studies the problem in rural East Pakistan, a densely-populated rice-producing area of South Asia. It is shown, using data on output and workers per acre and cropped acreage, that between 1951 and 1961 the degree of "disguised" unemployment increased sharply, amounting to some 20 percent of the 1961 labor force. This is attributed to the rapid population growth, which had begun two decades earlier, plus the fixed supply of other factors. The labor surplus that developed seems to have been largely "disguised" through work-sharing, that is, a reduction in average hours worked per worker.

DISGUISED" or "hidden" unemployment is one of the most fundamental concepts in development literature. Rosenstein-Rodan [33], Nurkse [22], Lewis [17], and Fei and Ranis [7] have assigned it a key role in interpreting economic backwardness and in suggesting how development can best be promoted through public policy. Yet a surprisingly small number of empirical investigations into the matter have been attempted, and these have not always supported the a priori theoretical assumption. Indeed, Kao, Anschel, and Eicher concluded that "to date, there is little reliable empirical evidence to support the existence of more than token—5 per cent—disguised unemployment in underdeveloped countries . . ." [14, p. 141].[1] On the other hand, the recent rather careful analysis of South Korea by Young Sam Cho finds a considerable amount of disguised unemployment [5]. Thus, the empirical results are contradictory.

This paper provides additional empirical evidence bearing on this question. More specifically, it attempts to construct the average and marginal product curves of agricultural labor for the province of East Pakistan for 1951 and 1961. The approach is an indirect one, using data on labor force, value of output, and cropped acreage. Our principal conclusion is that the product per marginal laborer in East Pakistan agriculture was positive in 1951, but that between 1951 and 1961 there developed an incremental "surplus" of about 20 percent of the labor force, in addition to whatever

[1] Jorgensen's recent survey of empirical results reaches the same conclusion [13, pp. 48–52].

WARREN C. ROBINSON *is professor of economics at The Pennsylvania State University.*

degree of surplus existed prior to 1951. The reconciliation of a growing surplus of workers with a positive marginal product was probably effected through decreases in the average work-week (hours worked per worker).[2]

A Brief Description of East Pakistan[3]

East Pakistan, one of the two provinces of Pakistan, is organized into 17 districts. Virtually the entire province is built-up alluvial deposits of the Ganges, the Brahmaputra, and the Meghna rivers, and their innumerable tributaries and branches. Its climate is tropical monsoon; its major crops, rice and jute, which are grown in nearly every district. There is considerable homogeneity in the physical land base and the structure of agriculture all across the province.

According to the 1961 census, nearly 80 percent of the agricultural labor force is made up of owner-cultivators or unpaid family labor. Some 95 percent of East Pakistan's 50 million people live in some 65,000 villages. In spite of its rural character, East Pakistan is densely settled. Its overall density approaches 1,000 per square mile, but two districts had 1961 densities of about 1700 per square mile. Population growth in East Pakistan has been rapid in the recent past. Although registration data on births and deaths is lacking, the 1951 and 1961 census data implied an annual average growth rate of over 2 percent. Moreover, there is evidence that the death rate has been falling while the birth rate has not, so that the growth rate may now be 3 percent per annum.[4] An ambitious family planning program has been launched, with government support, but no tangible results have yet appeared.

In summary, East Pakistan is made up for the most part of illiterate peasant cultivators who own their own land, live in small villages, and grow mostly rice, using their own labor. The area is densely settled and population is growing rapidly. Based on the conditions that generally are assumed to generate or at least to be associated with "disguised" unemployment, one would expect to find "surplus" labor in East Pakistan if it is to be found anywhere in the developing world.

Data and Methods Employed

Our data consist of (a) the agricultural labor force in East Pakistan for 1951 and 1961; (b) value of output in constant prices (1959–1960) for the major crops of the province; and (c) cropped acreage in East Pakistan for 1951 and 1961. Since these data were available by district, we have 17 observations for each year. Though limited, they make possible a cross-sectional analysis of the relationship between output and the two major inputs, land and labor. By expressing output and labor input on a per acre basis, it is possible also to estimate the average and marginal product functions of labor, land held constant.

---

[2] John Mellor has suggested that labor force may be thought of as the "stock" while man hours utilized should be seen as the "flow." Considerable confusion has arisen in the literature because of a failure to make this distinction [19].

[3] This section is based on the 1961 Census Report Summary [24] and on Professor Ahmad's authoritative volume [1].

[4] The growth rate may well be higher than this; see [15].

This approach assumes implicitly that the production relationships in the 17 separate districts are similar and that each district can be seen as an observation generated by a single provincewide production function. To the extent that production relationships in each district are not homogeneous, one would be troubled by our approach. More generally, this homogeneity problem arises whenever cross-sectional data are employed in estimating functional economic relationships, and there is no easy answer [9]. However, the objective evidence—soil types, rainfall, population density, crops grown, and so on—supports the assumption of underlying homogeneity of the production functions in the districts of East Pakistan [24, Ch. I; 27, Pt. I].

The major conceptual weakness of this approach is the absence of a figure for capital stock in both 1951 and 1961. However, this weakness may not be as serious as it appears at first glance. First, there is a general acceptance of the notion that capital in the usual Western sense (machinery, chemical fertilizers and pesticides, purchased seed, and so on) is unimportant as an input in the typical labor-intensive peasant agriculture situation of South Asia.[5] Capital there consists mainly of simple tools, built and maintained by the farmer himself, or of draft animals that also are locally "produced." Since these capital inputs probably change only as land under cultivation changes, we argue that land in our analysis is actually a surrogate for land-plus-capital. Second, there is the reassurance that the period 1951 to 1961 in East Pakistan was one of almost complete technological stability; that is, no major changes in technique, factor proportions, or level of investment seem to have occurred.[6]

Our labor force figures come from the 1951 and 1961 censuses, which differed in coverage and definition. The beginning labor force age was 10 years in 1951 and 12 years in 1961, requiring an adjustment of the 1961 data for our purposes.[7] Cropped acres and value of output are estimates compiled by the Provincial Department of Agriculture [28] and undoubtedly include many rough estimates. The physical output series were converted into value terms by multiplying them by the appropriate farm wholesale price indexes (again, as compiled by the Department of Agriculture), and the resulting value series was then expressed in constant prices, using the index of wholesale prices compiled by the Central Statistical Office. These prices and index series also undoubtedly contain many possible sources of error.

---

[5] Mellor writes: "The two prime inputs of traditional agriculture are land and labor. Capital is not only much less important in quantity, but also it is largely a direct embodiment of labor in the form of land improvements, water system and simple tools" [19, p. 37]. See also Mathur [18, p. 189]. Rao [31, p. 48] shows that in neighboring West Bengal in the middle 'fifties only about 18 per cent of gross value of output went to purchased inputs of all types, including bullocks and seed.

[6] Falcon and Gotsch write of the period under review as ". . . a stagnant era between Partition and the end of the First Plan Period . . ." [6, p. 31]. See also [21, pp. 243–244].

It can be argued that one should use as price weights the international price for the various crops, thus eliminating any distortions between 1951 and 1961 due to tariffs, domestic price controls, or temporary price movements occasioned by exogenous factors such as weather. However, fundamentally we are interested in the relative levels of 1951 and 1961, not in the absolutes, as we would be, for example, for international comparisons; and there is no evidence that the degree of price distortion for various commodities (compared with international prices) had changed between 1951 and 1961.

Finally, our total value of output represents, in fact, the output of rice, jute, and the other important crops. About 96 percent of the total cropped acreage is accounted for in the physical outputs underlying the value series. The unaccounted for residual component consists for the most part of minor food crops. We have no reason to think that including this element in our output series would affect trends or major conclusions.

Results and Interpretation

Table 1 presents yields per acre, by district, for 1951 and 1961. Average yield per acre rose from 210 rupees in 1951 to 240 rupees in 1961. The rapid increase in population was reflected in an increase from .41 to .51 in workers per cropped acre (Table 2). This ratio had apparently been quite stable in the .35 to .40 range prior to the 1951 census for a fairly long period of time.[8] The increase in workers per acre was also more uniform than changes in yield per acre. In 15 of the 17 districts, workers per acre increased; in one district there was no change; and in only one was there an apparent decrease in workers per acre.

Since we lack any measure of labor in man hours, our measure of marginal product of labor must be the changes in output per worker as

---

[7] Bean et al. [2] suggest further that, because of a change in the census question, unpaid female agricultural workers were more completely enumerated in 1961 than in 1951. The point is debatable, however, and we have made no adjustment for it.

[8] Thus, Blyn [3, p. 207] shows the following worker-per-acre ratios for greater Bengal: 1901–.385; 1911–.391; 1921–.415; 1931–.396. Our 1951 figure of .41 is quite consistent with these earlier data.

changes occur in average workers per acre of land. In view of the rather small number of observations available to us and their wide dispersion, we have resorted to a "smoothing" technique in an effort to bring out the underlying relationships. The average product per worker, as shown by our data (Table 3), was plotted against the corresponding values of workers per acre. A least-squares linear function was then fitted to these data, and the "expected" values of average products read from this function (Table 4). The marginal products per worker were then derived on

the basis of these "expected" average values. Thus, our average and marginal products are, in effect, "smoothed" estimates based on the data but giving more weight to the mean values of the distribution and less weight to the extreme cases.[9] Where P = output per worker, l = workers per acre, and Y = output per acre, our implicit production relationships are:

$$P = f\,(l) \text{ and } Y = P \times l$$

Since we define for our estimation equation:

$$P = \alpha - Bl$$

then we are assuming:

$$Y = l\,(\alpha - Bl) = \alpha l - Bl^2.$$

The results are interesting and quite plausible. They suggest that for 1951 and 1961 both the average and marginal product per worker fall continuously and rather sharply (Figures 1 and 2). Comparing 1951 with 1961, the average product per worker seems to have fallen from about 514 rupees to about 452 rupees, while workers per acre were rising from about .41 to .51. Within these overall changes there are some interesting differences. In 1951 marginal products ranged from about 384 to minus

---

[9] Our actual observations show a rather large amount of dispersion around the fitted least-squares lines. The standard errors of estimate ($S_{1.2}$) are: 1951—74.321; 1961—59.968. Combined with the means shown in Table 4 (1951—514; 1961—452), these yield indexes of relative dispersion (V) of: 1951—14.32; 1961—13.26. On the other hand, there is a significant relationship between the underlying variables, workers per acre and output per worker. The correlation coefficients (r_{12}) are: 1951—.7917; 1961—.7285. These are significant at the .05 level (N = 15).

528. Marginal product became negative at about 550 average product and when about .40 workers per acre were employed. In 1961 the average and marginal functions have both flattened out and shifted slightly to the left, with the result that the marginal product distribution has less range (from about 400 to minus 270) and fewer negative values. The marginal products become negative when some .75 workers or more per acre are employed or when the average product is about 300 rupees per worker.

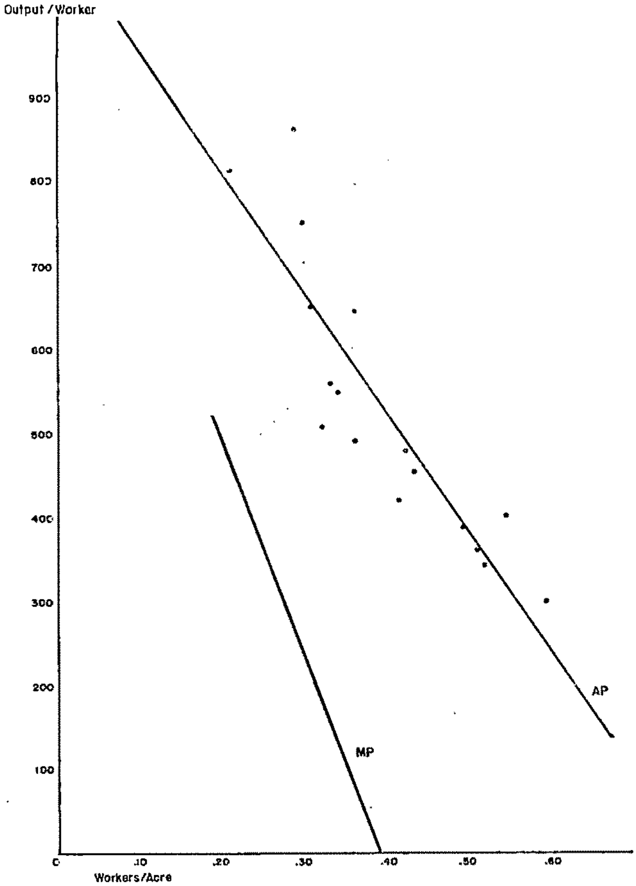

Figure 1. **Average and marginal productivity of agricultural workers. East Pakistan, 1951**

"Work-sharing" as an explanation

The nature of the shift in both average and marginal functions suggests an interpretation that is consistent with what one might expect to occur in a small-scale, family-centered, peasant agricultural sector subjected to rapid population growth. Thus, let us assume that the pre-1951 setting in agriculture was "efficient" in the sense that cultivators were applying about the "right" amount of labor (measured in man hours) per acre, given the technology of production. The average work week (hours worked per worker) would have been optimal even though perhaps below a Western-style "normal" work week (thus implying already existing "disguised" unemployment). Assume that all additional workers "claim" at least a subsistence share of total output because of family ties. Assume

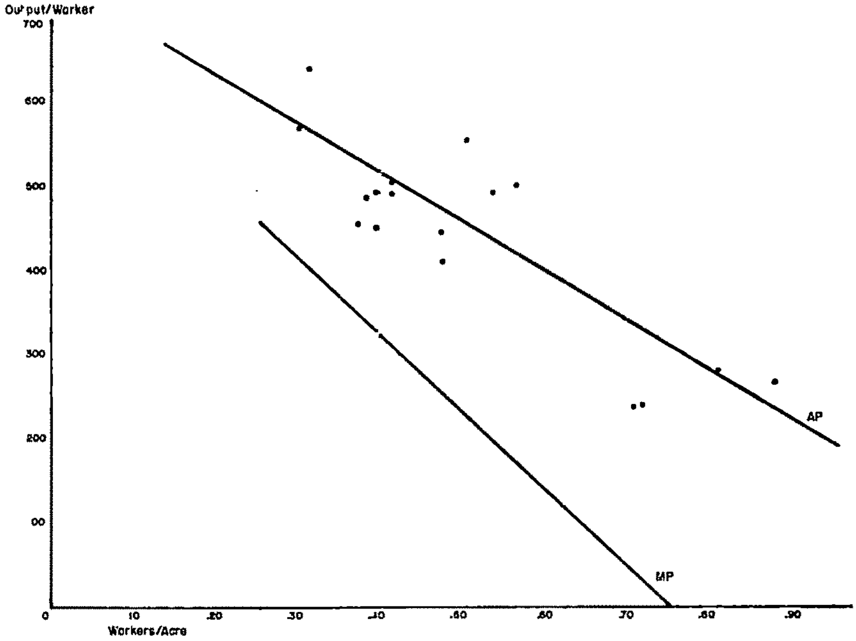

Figure 2. **Average and marginal productivity of agricultural workers, East Pakistan, 1961**

further that leisure has a positive value to the cultivators, so that, given a choice of working longer or shorter hours for the same income, they would prefer shorter hours. In this situation, any increase in workers will reduce the average hours worked per worker, as well as the average product per worker, even while not affecting the average product per man hour or per standard man day. Disguised unemployment would increase. "Work-spreading" would occur so that the marginal product per worker remained positive even while the number of workers increased. This would show up graphically as a "flattening out" of the average and marginal product functions of labor over time as hours of work per worker fell. Only when numbers of workers had increased to such an extent that average product per worker was approaching marginal product and both were near the subsistence level would further "work-spreading" become impossible. Past this point, either negative (or at least below subsistence) marginal products would begin to appear or the institutional arrangements under which added workers were guaranteed a claim against output would begin to break down and overt unemployment appear.

This interpretation is plausible and consistent with the results obtained above for East Pakistan.[10] The period of rapid natural population increase in East Pakistan dates back only to the thirties when death rates began to fall slowly. It would probably have required several decades for the population growth to have begun to build up enough to affect the man/land ratios. However, by 1951, the stable "efficient" factoral balance in agriculture was disturbed. The negative marginal products per worker actually observed can thus be seen as an accidental result of too many laborers (and too many labor hours) being applied to the land. By 1961, however, an adjustment—even to the continuing population pressure—had occurred and a new "efficient" employment of the existing labor force had come about through a reduction in hours worked per worker.[11]

It should also be noted that some genuine labor *intensification* per acre may have increased because of exogenous changes, such as an incentive effect created by the land reform of 1958,[12] or changes in non-labor inputs, such as increased irrigation in the dry season, or more use of fertilizers. However, if some "surplus" already existed because of previous work-sharing practices, then labor intensification could have occurred in response to the exogenous changes even without the growth in the labor force.

Extent of disguised unemployment

What do these results imply about the magnitude of "disguised" unemployment in East Pakistan in 1951 and 1961? During that decade the total labor force grew by 3.6 million. Cropped acreage grew by 1.3 million which, given the 1951 workers per acre ratio of .41, required only 600,000 new workers. The additional 3 million new workers actually employed increased the workers per acre ratio to .51 and decreased the average product per worker. Had the 1951 relationships between labor inputs and output per worker (the average and marginal product curves per acre) also held for 1961, the actual 1961 workers per acre ratio of .51 would have resulted in a province-wide average product per worker of about 360 rupees and a total output of about 5,200 million rupees, or a drop of about 20 percent from the actual 1961 total output. Since the average workers per acre ratio in 1951 of .41 was also the point at which negative marginal products began to occur, one can argue that the entire 3 million workers added between 1951 and 1961 were surplus. This would amount to some 20 percent of the 1961 labor force.

---

[10] This interpretation also receives some indirect support from surveys conducted in East Pakistan in 1961. Nurul Islam, summarizing these, writes: "With a smaller size of holdings per head, i.e., with a larger working population per acre, less time seems to be spent per head on the farms and thus more workers can be accommodated per acre. This may indicate a certain amount of work spreading to provide employment for a larger active population . . ." [12, p. 249].

[11] A. K. M. Ghulman Rabbani [30] has studied the problem of underemployment in East Pakistan using a completely different approach. Using a standard man-day of eight hours and an estimate of marginal productivity per man-day, Rabbani calculated the output of rise in East Pakistan in 1964–65. This was then compared to the actual labor available and on this basis . . . "it is seen that nearly 40% of the labour employed . . . was surplus . . ." [30, p. 241]. These results are not inconsistent with those reached here. Our major point is that the magnitude of the true "surplus" is "disguised" by a shift in the average hours worked per worker so that the "required" labor inputs are furnished by all the "available" laborers.

[12] The land reform in question did not result in a radical break-up of large-scale estates with the consequent risks of a drop in output. Instead, it chiefly vested ownership rights in the small-scale cultivators already tilling the land, many of whom obtained the land *de facto* following Partition in 1947. Thus, one could presume the effects were purely favorable.

This is an *incremental* measure of surplus, and it can be argued that even the 1951 worker per acre ratio reflected a substantial amount of surplus. Mathur, for example [18, p. 187], cites earlier studies suggesting that in 1951 disguised unemployment in neighboring West Bengal might have been as high as 33 percent of the agricultural labor force. Much of this, however, was seasonal in nature, and this seasonal element would presumably remain constant and not affect our measure of labor surplus. The remaining disguised unemployment in 1951 presumably took the form of a less than full employment average work-week, measured in hours worked per worker. Our interpretation of the 1951 and 1961 shifts suggest that this type of disguised unemployment grew markedly during the period and that the 20 percent surplus of workers who entered the work force were largely absorbed by work-sharing.

Summary and Implications

Our analysis suggests that from a rather static, long-run kind of equilibrium in factor proportions in 1951, the effect of labor force growth in East Pakistan between 1951 and 1961 was to introduce a surplus of workers amounting to as much as 20 percent of the 1961 labor force. This surplus was "hidden" by a rearrangement of hours worked in agriculture that provided an opportunity for each member of the work force to produce at least enough for his subsistence. This surplus was in addition to whatever surplus existed in 1951 before the impact of population growth was felt.

Our data also suggest that the increases in total output that occurred between 1951 and 1961 in East Pakistan were the result of small increases in the cropped acreage as well as in the yield per acre, the latter chiefly being a reflection of greater intensity of cultivation.

It must also be noted that this analysis and these conclusions refer strictly to the period 1951–1961. The striking changes that occurred in the Second Five-Year Plan period (1960–1965) are no part of our story [6].

The Effect of Technology on the Farm Labor Market*

LARRY L. BAUER

The primary purpose of this paper was to estimate the time path of the effect of technology, as measured by research and extension expenditures, on the farm labor market. A distributed lag function was estimated by incorporating the concept of rational distributed lag functions, as developed by Dale Jorgenson, into a simultaneous equation model of the farm labor market. The estimated lag distribution, even though quite long, had a "hump" as hypothesized. The implicit production function implied a positive payoff to the economy from research and extension expenditures.

THE PRIMARY purpose of this study was to investigate the time path of the effect of technology on the farm labor market; that is, a distributed lag function relating the effect of a change in technology to time was estimated. A lag function yields a set of weights, each of which shows the portion of total effect that occurs within a given time period. Since the total effect is to be distributed through time, the weights by necessity must add to one.

To date there is little behavioral theory to aid in estimating a lag distribution. Therefore, as in other studies, the lag distribution in this study was estimated by imposing a family of general distributions on the data and determining the one that in some sense "best" fit the data.

This study was based principally on papers by Wallace and Hoover [10] and Gisser [3]. However, whereas they used cross-sectional data, this study used both cross-sectional and time-series data.

Distributed Lags

The concept of rational distributed lag functions, as developed by Jorgenson [8], was used to estimate the lag distribution. This technique, unlike most other methods of estimation, does not restrict the lag distribution to a particular pre-specified configuration; it allows the data itself to determine the configuration of the lag distribution by estimating parameters of the general lag function concurrently with the parameters of the basic model.

An article by Griliches [6], which surveys various techniques that have been used to estimate lag functions, contains a summary of the concept of

* This article is a report of research done by the author while a graduate assistant at North Carolina State University and is reported more fully in his unpublished Ph.D. dissertation. The author wishes to extend appreciation to T. D. Wallace and D. M. Hoover for reviewing a previous draft of this paper.

LARRY L. BAUER *is assistant professor of agricultural economics at The University of Tennessee.*

rational distributed lag functions that may be easier for the practical researcher to follow.

The Structural Model

The model consisted of two structural equations:

(1) Demand for farm labor:

$$Q_{it} = f(W_{it}, S_{it}, E_{it}, R_{it})$$

(2) Supply of farm labor:

$$W_{it} = g(Q_{it}, \overline{W}_{it}, U_{it})$$

where

Q_{it} = quantity of farm labor = total man hours of farm labor, including operator, family, and hired labor;
W_{it} farm wage rates = wage rate per hour for hired farm labor, in 1957–1959 dollars;
R_{it} = technology = state and federal expenditures for experiment station research and the cooperative extension service;
S_{it} = stock of land = stock of land excluding effects of farm programs, measured in 1957–1959 dollars;
E_{it} = other expenditures = current operating expenses, excluding expenditures for hired farm labor, measured in 1957–1959 dollars;
$\overline{W}_{it}$ = alternative wage rate = hourly wage rate for workers on manufacturing payrolls; measured in 1957–1959 dollars;
U_{it} = rate of unemployment = insured unemployment as a percent of average covered employment; and

where the subscripts

$i = 1 \ldots 39$ for 39 states or groups of states, and
t = time, for the years 1951 . . . 1961.

Two variables considered by Wallace and Hoover were not considered here, namely age and education, because no adequate measure for these variables exists for intercensal years.

Data for more than eleven years would have been desirable, but adequate data do not exist prior to 1949 and the 1964 Census of Agriculture data were not yet available at the time of this study. However, the assumption was made that each state has the same lag distribution, thus allowing the estimation of a lag distribution with data from so few years.

The variables Q_{it} and W_{it} were treated as endogenous and the rest were assumed to be exogenous, or predetermined. The equations were assumed to be additive, with the variables in logarithms. Mathematically stated, the structural model is:

Demand: $Q_{it}=\beta_0+\beta_1 W_{it}+\beta_2 S_{it}+\beta_3 E_{it}+A(L)\,\beta_4 R_{it}$
Supply: $W_{it}=\delta_0+\delta_1 Q_{it}+\delta_2 \overline{W}_{it}+\delta_3 U_{it}$

where all the variables are in logs and $A(L)$ is a lag polynomial in the rational form $N(L)/D(L)$ and L is the so-called lag operator.

To the extent that agriculture in a single state is competitive with other states, it is reasonable to take product demand as perfectly elastic in an analysis of cross-section data [3, 10]. When time series variation is introduced into the analysis, as in the present paper, the assumption of exogeneity of product price is less tenable. A formal attempt to minimize the chance for simultaneous equation bias would have required specifying additional equations for demand and supply in the agricultural product as well as the farm labor market, thus conditioning the subsequent reduced form estimation. However, it was decided that the increased complexity of additional equations was less desirable than the risk of simultaneous equation bias.

Reduced Form Equations

In order to estimate the parameters of the structural equations, two reduced form equations had to be estimated first, as follows:

$$Q_{it} = \Pi_{10} + \Pi_{11}S_{it} + \Pi_{12}E_{it} + A(L)\Pi_{13}R_{it} + \Pi_{14}\overline{W}_{it} + \Pi_{15}U_{it}$$

$$W_{it} = \Pi_{20} + \Pi_{21}S_{it} + \Pi_{22}E_{it} + A(L)\Pi_{23}R_{it} + \Pi_{24}\overline{W}_{it} + \Pi_{25}U_{it}$$

It should be noted that the rational lag function, $A(L)$, relating technology to the endogenous variable in the structure, remains invariant in the reduced form and appears as the coefficient of R_{it} in both equations.

Distributed Lag Function

As mentioned, there is little behavioral theory available to restrict the potential family of acceptable lag distributions. Therefore, the problem was one of finding the lag function yielding the set of weights that in some sense best fits the data. Three criteria suggested themselves in determining an acceptable distribution: (1) The coefficient of determination or R^2 for the estimated reduced form equation. This was an obvious choice since estimates that explain a large portion of variation in data are desirable. (2) Reasonableness of the estimated lag distributions, since some sets of estimates of the lag parameters can give negative weights, or weights that have no finite sum.[1] (3) The signs and magnitudes of the structural parameter estimates. An idea of magnitudes of the estimates was obtained from studies using either cross-sectional or time-series data [10, 9].

---

[1] When the demand for farm labor is viewed as a value of marginal product relationship, it can be shown that the lag distribution $A(L)$ also applies to the technology variable in its effect on agricultural output in the production function. Thus, if the weights of the lag distribution have no finite sum, this would imply an infinite rate of return to a dollar spent on technology. Hence, such a lag distribution was ruled as implausible.

A "family" of five second-order rational lag functions, $P(L) = N(L)/D(L)$ were investigated (Table 1).[2] Since function 5 contains the largest number of lag parameters, it was used to develop a general mathematical statement that serves for all five functions. This is presented in the Appendix. With function 5 imposed on the data and after the mathematical manipulations are carried out, each reduced form equation contains 17 variables and a constant term. The coefficients are combinations of the reduced form parameters, the Π's; and the lag distribution parameters *a*, *b*, *c*, and *d*.

Table 1. Family of second-order lag functions

Function	$N(L)$	$D(L)$
1	1	$1-cL-dL^2$
2	$1+aL$	$1-cL-dL^2$
3	$1+aL+bL^2$	1
4	$1+aL+bL^2$	$1-cL$
5	$1+aL+bL^2$	$1-cL-dL^2$

Restricted Estimation

Estimation of the reduced form equations involved estimating ten reduced form parameters, two constant terms, and up to four lag distribution parameters, depending on which lag function was imposed on the data. A restriction implicit in the model was that the lag distribution parameters be the same in both equations. To do this, the equations were combined and estimated at the same time in one large regression. This was done by the following technique. Consider the two equations:

$$\begin{aligned} Y_{1t} &= \alpha Z_{1t} + \beta Z_{2t} \\ Y_{2t} &= \alpha Z_{3t} + \gamma Z_{4t} \end{aligned}$$

It is implicit that the estimate for α be the same in both equations. In order to accomplish the estimation subject to this restriction, the equations are combined as follows:

$$\begin{array}{ccc} Y & & \begin{array}{ccc} X_1 & X_2 & X_3 \end{array} & B \\ \begin{bmatrix} Y_{1t} \\ \\ Y_{2t} \end{bmatrix} & = & \begin{bmatrix} Z_{1t} & Z_{2t} & 0 \\ & & \\ Z_{3t} & 0 & Z_{4t} \end{bmatrix} & \begin{bmatrix} \alpha \\ \beta \\ \gamma \end{bmatrix} \end{array}$$

The vectors of data for the two dependent variables are combined into one

---

[2] The polynomial $P(L)$ is an intermediate step in the derivation of the desired polynomial $A(L)$.

"long" vector, Y. The vectors of data for Z_1 and Z_3 also are combined into a "long" vector, X_1. However, the vector of data for Z_2 is regressed only on Y_1 and the data for Z_4 is regressed only on Y_2. The equation to be estimated is, in matrix notation,

$$Y = XB$$

where the matrix X is made up of the vectors X_1, X_2, and X_3. This equation can be estimated by least squares and will give one estimate of α, and unique estimates of β and γ subject to the restriction that α has the same value in both equations.

Thus, the combined equation estimated in this study is, in matrix notation,

$$Y = XB$$

where

$$Y = \begin{bmatrix} Q_{it} \\ W_{it} \end{bmatrix}$$

and the matrix X is made up of the vectors X_1, X_2, $\cdots X_{34}$, which are shown in Table 2. The matrix B is the vector of parameters to be estimated.

The dimensions of these matrices are:

$$\begin{aligned} Y &= 858 \times 1 \\ X &= 858 \times 34 \\ B &= 34 \times 1 \end{aligned}$$

The equation to be estimated was:

$$\begin{aligned} Y = {} & \Pi_{10}X_1 + \Pi_{20}X_2 + cX_3 + dX_4 + \Pi_{11}X_5 + \Pi_{21}X_6 - c\Pi_{11}X_7 - c\Pi_{21}X_8 \\ & - d\Pi_{11}X_9 - d\Pi_{21}X_{10} + \Pi_{12}X_{11} + \Pi_{22}X_{12} - c\Pi_{12}X_{13} - c\Pi_{22}X_{14} \\ & - d\Pi_{12}X_{15} - d\Pi_{22}X_{16} + \Pi_{13}X_{17} + \Pi_{23}X_{18} + a\Pi_{13}X_{19} + a\Pi_{23}X_{20} \\ & + b\Pi_{13}X_{21} + b\Pi_{23}X_{22} + \Pi_{14}X_{23} + \Pi_{24}X_{24} - c\Pi_{14}X_{25} - c\Pi_{24}X_{26} \\ & - d\Pi_{14}X_{27} - d\Pi_{24}X_{28} + \Pi_{15}X_{29} + \Pi_{25}X_{30} - c\Pi_{15}X_{31} - c\Pi_{25}X_{32} \\ & - d\Pi_{15}X_{33} - d\Pi_{25}X_{34} \end{aligned}$$

This was a regression with 858 observations and 34 variables. Since there were sixteen parameters to be estimated in this most general case, the estimation equation was overidentified, as was the case when the other four lag functions were imposed on the data.

Estimation of the Reduced Form Parameters

The equation is nonlinear with respect to the parameters. A technique of nonlinear estimation exposited by Clark Edwards [1] was used to get individual estimates of each of the parameters.

Table 2. The vectors, X_1, in the matrix X

10	$\begin{pmatrix}0\\S_{i,t-2}\end{pmatrix}$	22	$\begin{pmatrix}0\\R_{i,t-2}\end{pmatrix}$	34	$\begin{pmatrix}0\\U_{i,t-2}\end{pmatrix}$
11	$\begin{pmatrix}E_{it}\\0\end{pmatrix}$	23	$\begin{pmatrix}\overline{W}_{it}\\0\end{pmatrix}$		
12	$\begin{pmatrix}0\\E_{it}\end{pmatrix}$	24	$\begin{pmatrix}0\\\overline{W}_{it}\end{pmatrix}$		

Weights of the Lag Distribution

The techniques discussed allowed unique estimates to be obtained for all the reduced form equation parameters and the lag distribution parameters. Given the parameters of the chosen lag distribution, the series of weights relating the effects of a change in technology through time could then be derived. This was done by carrying out the implicit division in $P(L)=N(L)/D(L)$, which yields a polynomial in the lag operator L, generally,

$$p_0 + p_1L + p_2L^2 + \cdots + p_tL^t$$

These p_i's are an approximation of the desired weights, since a restriction placed on the desired polynomial was that it sum to one. The series will not necessarily sum to one, and in all probability, it will not. However, it can be made to do so by dividing each element in the series by $\sum_{t=0}^{\infty} p_t$. Therefore, the weights desired, or coefficients of the polynomial A(L) are:

$$\frac{p_0}{\Sigma p_t} + \frac{p_1}{\Sigma p_t} + \cdots = w_0 + w_1 + w_2 + \cdots = 1$$

Griliches [6, p. 23] derives the weights in a slightly different manner, but the results are the same.

Estimation of the Structural Parameters

Since one of the criteria for selection of a lag distribution was the reasonability of the associated estimates of the structural parameters, a method which used only 1959 data was used to estimate the structural parameters in order that they might be compared with the estimates of similar coefficients in the Wallace-Hoover [10] study.

The first step was the computation of a new technology variable, R_{it}^*, which was essentially a weighted average of the data for the original R_{it} variable for 1959 and the 18 previous years, with the weights for calculating the average being the yearly weights from each of the five lag functions. In other words, the five estimated lag distributions were imposed on the technology variable.

From this point estimation was the same as in the Wallace-Hoover study, with one difference. The latter used an arbitrary lag function[3] to weigh the effect of previous research and extension expenditures, whereas this study used as weights those yearly weights generated by the five lag functions, each estimated by combining cross-section with time-series data. A set of estimates for the structural parameters was obtained for each of the five lag functions. Since the system of structural equations was overidentified, a technique similar to two-stage least-squares[4] was necessary.

Specifically, the estimation procedure was to use first the estimates of Π_{11}, Π_{12}, Π_{13}, Π_{14}, Π_{15}, a, b, c, and d to get predicted values of Q_{it}, and then the estimates Π_{21}, Π_{22}, Π_{23}, Π_{24}, Π_{25}, a, b, c, and d to get predicted values of W_{it}. The estimates of the structural parameters for the supply equation were then obtained from the regression of

$$W_{it} \text{ on } \hat{Q}_{it},\ \overline{W}_{it},\ U_{it}$$

---

[3] Wallace and Hoover [10] used a five year geometric mean of research and extension expenditure data.

[4] This is a technique discussed in econometrics textbooks, *e.g.*, Johnston [7].

and the estimates of the structural parameters in the demand equation were obtained from the regression of

$$Q_{it} \text{ on } \hat{W}_{it}, S_{it}, E_{it}, R_{it}^*$$

where

$$t = 1959$$

$$R_{it}^* = A(L)R_{it}$$

and the "hats" indicate predicted values.[5]

The Estimated Lag Distribution

Estimation was carried out according to the procedures described. The lag function was selected on the basis of the three criteria established, with the result that functions 4 and 5, which were of very similar configuration, were chosen. Function 3 was eliminated because it had the lowest R^2 of the five functions, as well as negative weights in the lag distribution. The R^2's of the other four functions were not significantly different, and all had reasonable lag distributions. Functions 4 and 5 were chosen on the basis of the reasonability of the estimates of the structural parameters. Functions 1 and 2 were eliminated because they implied negative supply elasticities.

The estimated lag functions were, in the case of function 4:

$$P(L) = \frac{1 + 3.169L - 3.867L^2}{1 - .985L}$$

and in the case of function 5:

$$P(L) = \frac{1 + 2.970L - 3.698L^2}{1 - 1.061L + .075L^2}$$

It should be recalled that each of these polynomials must be divided by its respective sum in order to generate the desired weights; that is,

$$A(L) = \frac{P(L)}{\Sigma p_t}$$

The mean of function 4 is 49.2 years and the mean of function 5 is 45.1 years.[6] The median of function 4 is approximately 27 years; for function 5, approximately 22 years. These two distributions are shown graphically in Figure 1, and the weights for several years are presented in Table 3.

---

[5] Regression was done both ways, *i.e.*, Q was regressed on $\hat{W}$ and then W on $\hat{Q}$ for both demand and supply. The two sets of estimates for the demand relationship were very similar, but some differences did exist in the estimates of the supply relationship.

[6] See Griliches [6, p. 18] for procedure used in finding means of distributed lag functions.

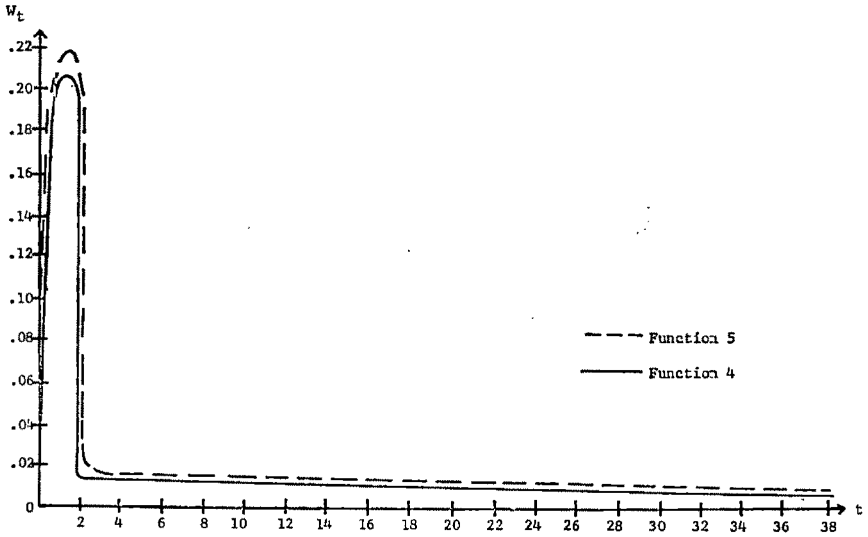

Figure 1. Configuration of the estimated lag distribution

As hypothesized, the estimated lag distribution has a "hump," that is, the greatest effect within any given time period occurs after the passage of time rather than in the initial period as would be the case had a Koyck or monotonically declining function been imposed on the data. This conforms with findings of other studies, such as Griliches [4] and Evenson [2], and would seem to be a reasonable phenomenon. The results here indicate that the largest effect occurs in the second time period, in which an excess of 20 percent of the total effect takes place. The weights of the distribution then decline to a point where there is very little change from one period to the next.

The estimated lag distribution is quite long which, intuitively, seems somewhat unrealistic. However, when this is weighed against the positive characteristics—the distribution has a hump, the sum of the weights is finite, and the weights are all positive—the overall results seem favorable. A possible explanation of the length is that the estimated distribution is a convolution, or combination, or more than one lag distribution. At a minimum, it would seem that the estimated distribution could be considered as a convolution of the lag between the funding of research and its subsequent conclusion and the lag between conclusion of the research and the time it is put into practice. In addition, the technology variable used here considers not only funds for research but funds for extension activities as well; therefore, the estimated lag distribution could also be considered to contain the convolution of the separate lag distributions for research and extension. These convolutions would seem to tend to lengthen the lag distribution.

Table 3. The numerical weights, w_t, of the estimated lag distributions

Another reason for the long distribution is likely to be the assumption made in this study that a common lag distribution existed for all states. In reality, in all probability, there are pronounced differences in the lag distribution for each individual state. This may be due to differences in the production periods associated with the important farm products of different states, for example, it would take longer for the results of particular research to become apparent in a state that has primarily a woodland agriculture than in a state that produced primarily small grain.

Some of the considerations discussed here are illustrated in the study by Griliches [4] on hybrid corn. He considered one particular area of research and did not consider extension activities. However, since both his work and this study consider research activities as a measure of technical change, some comparison can be made. In the first place, the Griliches study emphasizes the likelihood that a common lag distribution does not hold for all states. He showed that each state accepted hybrid corn at a different rate and that twelve years elapsed between when the earliest and the latest state had 10 percent of their total corn acreage in hybrid corn.

The Griliches study also exemplifies the fact that the distribution estimated in this study is a convolution of more than one distribution. He dealt with two lag distributions: the lag between the availability of hybrid corn and its use by farmers, and the lag between states in the use of hybrid corn.

In the Griliches study, the median lag of the acceptance of hybrid corn within a particular state ranged from five to ten years. The median lags for the two distributions estimated in this study were 22 and 27 years. These medians would seem rather comparable inasmuch as the distribution estimated in this study was a convolution of several distributions, included all research expenditures as well as extension, and assumed a common distribution for all states.

As mentioned, the lag functions (or, in actuality, logistic growth curves) estimated by Griliches implied that a "hump" existed in the distribution; that is, the maximum effect occurred sometime after the initial time period.

Evenson [2] considered distributions of two shapes—monotonically declining and an inverted "V". He found the inverted "V" best fit the data. This is consistent with the "humped" distributions estimated in this study and by Griliches. However, the mean lag in the Evenson study was six to seven years in comparison with the 45 to 50 year mean of the distribution estimated in this study.

Structural Parameters

The estimates of the structural parameters are given in the following equations:

$$\text{Demand: } Q_{it} = -.864 - 1.482\hat{W}_{it} + .221S_{it} + .476E_{it} + .317R_{it}^{*}$$

$$\text{Supply: } W_{it} = -1.043 + .0005\hat{Q}_{it} + 1.199\overline{W}_{it} - .049U_{it}$$

Standard errors are not reported since the standard errors from the two-stage least-squares estimation presented difficult problems of interpretation.[7]

The estimates of the coefficients of the demand equation are fairly comparable with those from the Wallace-Hoover [10] study. The signs are all consistent with what one would have expected. The inference from the estimation equation for demand is that, assuming a perfectly elastic supply of labor and a perfectly elastic demand for farm output, a 10 percent increase in technology, that is, a 10 percent increase in research and extension expenditure, will lead to a 3.2 percent increase in the quantity of farm labor demanded. Alternatively, the implication is that a 10 percent increase in technology will lead to a 2.1 percent increase in the farm wage rate if the quantity of farm labor is held constant. These are the total, or long run, effects of a change in technology. The lag distribution gives the portion of the total effect that occurs within any given year.

---

[7] The technique used was only similar to two-stage least-squares. The estimation of the reduced form and the lag distribution parameters, used to calculate R_{it}^{*}, $\hat{W}_{it}$, and $\hat{Q}_{it}$, used both the cross-sectional and time-series data, whereas the structural parameters were estimated using only 1959 data. This presented an interpretation problem with respect to the standard errors calculated in the two-stage least-squares estimation of the structural parameters. For those who may wish to make interpretations, all the structural parameter estimates, with the exception of the coefficients of $\hat{Q}_{it}$ and U_{it} in the supply equation, were significant at least at the 95% level when the calculated standard errors were considered.

The signs of the estimates of the coefficients in the supply equation are all consistent with what one would have expected. The estimate of the coefficient for the quantity of farm labor variable is much smaller than the comparable coefficient from the Wallace-Hoover study.

Adjustment for the Product Market

The estimate of the technology parameter implies that an increase in research and extension expenditures has a positive effect on gross return to farm labor since it has a positive effect on the quantity of labor demanded. However, this estimate was made given the assumption of perfect elasticity of product demand. Estimation was carried out on the premise that the simultaneous equation bias would not be too great by treating product prices as exogenous. However, in making inference from the estimates, one need not continue the premise of exogeneity of product prices.

A technique used by Gisser [3, p. 590] and Wallace and Hoover [10, p. 330] was used to adjust the research and extension coefficient for different product demand elasticities. This technique is based on the assumption that the demand relationship estimated is the value of marginal product for labor. From this a production function can be determined. By assuming a particular form for the product demand relationship, stating the demand for labor as generally being marginal physical product times product price, doing the appropriate substitution, and finding $\partial Q_{it}/\partial R_{it}^*$, the desired adjustment factor is obtained. It is

$$b_4^* = b_4 \frac{(\epsilon + 1)}{(\epsilon + 1 + b_1)}$$

where

b_4 = original estimate of research and extension coefficient,
b_4^* = research and extension coefficient adjusted for different product demand elasticities,
ϵ = assumed product demand elasticity, and
b_1 = coefficient of $\hat{W}_{it}$ in labor demand relationship.

Table 4 gives values of the coefficient adjusted for various elasticities. The technology coefficient becomes negative when the value of the elasticity coefficient becomes less than one in absolute value, that is, when the product

Table 4. Coefficient of technology variable for alternative product demand elasticities

Product demand elasticity	Coefficient of technology variable
0	−.658
− .10	−.490
− .25	−.325
− .50	−.161
− .75	−.064
−1.00	0
−1.25	.046
−1.50	.080
−1.75	.107
− ∞	.317

demand becomes inelastic. For example, with an inelastic product demand of −.10, a 10 percent increase in technology would decrease the quantity of labor demanded by 4.9 percent. The implication is that by relaxing the assumption of infinite product demand and considering inelastic demand relationships for farm production, the increase in technology has a negative effect on farm income. This is so because the increase in technology increases total farm output, and this, given a very inelastic product demand relationship, depresses farm prices; hence, the value of marginal product or demand for labor also declines, causing a decline in personal farm income with a given labor supply relationship.

The Implicit Production Function

An intermediate step in the development of an adjustment for alternative product demand elasticities was that of deriving the implicit production function from the labor demand relationship. The production function for the coefficient estimates obtained in this study is

$$Y_{it} = .325Q_{it} + .149S_{it} + .322E_{it} + .214R_{it}^*$$

where Y_{it} = total farm output, the constant term is omitted, and all variables are in logarithms. This is a Cobb-Douglas type exponential production function and the sum of the coefficients is 1.01, implying essentially constant returns to scale. An implication of this production function, similar to a result by Griliches [5], is that there is a positive payoff to the economy from research and extension expenditures; in other words, the coefficient of R_{it}^* is positive. An extension of this paper will be to determine the internal social rate of return to research and extension expenditures using the estimated lag distributions and various product demand assumptions.

Appendix

Taking the most general lag function, number 5:

$$P(L) = \frac{N(L)}{D(L)} = \frac{1 + aL + bL^2}{1 - cL - dL^2}$$

and imposing it on the research and extension variable, R_{it}, the result in the reduced form equations is

$$Q_{it} = \Pi_{10} + \Pi_{11}S_{it} + \Pi_{12}E_{it} + \Pi_{13}\frac{1 + aL + bL^2}{1 - cL - dL^2}R_{it} + \Pi_{14}\overline{W}_{it} + \Pi_{15}U_{it}$$

$$W_{it} = \Pi_{20} + \Pi_{21}S_{it} + \Pi_{22}E_{it} + \Pi_{23}\frac{1 + aL + bL^2}{1 - cL - dL^2}R_{it} + \Pi_{24}\overline{W}_{it} + \Pi_{25}U_{it}$$

After the implicit multiplication is carried out and the variables lagged according to the lag operators, the results are:

$$\begin{aligned}
Q_{it} = {} & \Pi_{10} + cQ_{i,t-1} + dQ_{i,t-2} + \Pi_{11}S_{it} - c\Pi_{11}S_{i,t-1} - d\Pi_{11}S_{i,t-2} \\
& + \Pi_{12}E_{it} - c\Pi_{12}E_{i,t-1} - d\Pi_{12}E_{i,t-2} + \Pi_{13}R_{it} + a\Pi_{13}R_{i,t-1} \\
& + b\Pi_{13}R_{i,t-2} \\
& + \Pi_{14}\overline{W}_{it} - c\Pi_{14}\overline{W}_{i,t-1} - d\Pi_{14}\overline{W}_{i,t-2} + \Pi_{15}U_{it} \\
& - c\Pi_{15}U_{i,t-1} - d\Pi_{15}U_{i,t-2} \\
W_{it} = {} & \Pi_{20} + cW_{i,t-1} + dW_{i,t-2} + \Pi_{21}S_{it} - c\Pi_{21}S_{i,t-1} - d\Pi_{21}S_{i,t-2} \\
& + \Pi_{22}E_{it} - c\Pi_{22}E_{i,t-1} - d\Pi_{22}E_{i,t-2} + \Pi_{23}R_{it} + a\Pi_{23}R_{i,t-1} \\
& + b\Pi_{23}R_{i,t-2} \\
& + \Pi_{24}\overline{W}_{it} - c\Pi_{24}\overline{W}_{i,t-1} - d\Pi_{24}\overline{W}_{i,t-2} + \Pi_{25}U_{it} - c\Pi_{25}U_{i,t-1} \\
& - d\Pi_{25}U_{i,t-2}
\end{aligned}$$

These equations can be made into those appropriate for function 2, for example, by setting the parameter b equal to zero.

Mergers and Diversified Growth of Large Grain Firms*

DAVID W. COBIA AND PAUL L. FARRIS

Firm growth by merger has received considerable attention because of its potential effects on industry organization and, in turn, economic performance. Early mergers often increased horizontal concentration, but recent ones appear to have been more associated with vertical and conglomerate integration. This study of 35 large firms in grain processing and merchandising industries showed that growth by merger was relatively larger from 1954 to 1963 than from 1940 to 1954. All but eight of the 35 firms became more highly diversified. Increasing diversification was associated positively with initial firm size and the relative importance of external growth.

LARGE business firms in the United States are becoming increasingly diversified,[1] and this trend is giving rise to new issues of antitrust policy. Diversification appears to have been associated, at least in part, with growth by merger or acquisition, sometimes called external growth.

In the past, merger movements, or periods of active external growth, have produced more dramatic changes in industrial organization than internal growth, which refers to capital invested in new plants and equipment [6]. This has occurred even though internal growth, while varying widely over time and among firms, has accounted for the larger portion of total growth.

Mergers early in this century were associated mainly with greater horizontal concentration [8], whereas those occurring later, especially acquisitions by large firms, appeared to be more related to increases in vertical and conglomerate integration. As a consequence, the particular effects of recent mergers may differ significantly from those of earlier periods, but it is likely that merger activity and public policy toward mergers will continue to have a pronounced effect on the rate and direction of structural change in American industry.

It is not known precisely how widespread diversification is among firms that process and distribute agricultural products, why it has come about, what the trends are, nor what the consequences may be. This study was undertaken to measure and analyze growth by merger of large firms active in a major sector of the agricultural economy—the processing and merchandising of grains and grain products. Particular emphasis was

[1] For example, Gort found that 111 of the largest companies in the United States added 40 to 50 products a year from 1929 to 1950, but more than twice as many each year from 1950 to 1954 [5, p. 46].

DAVID W. COBIA *is assistant professor of agricultural economics at North Dakota State University.* PAUL L. FARRIS *is professor of agricultural economics at Purdue University.*

given to interrelations among firm size, external growth, and diversification.

Selection of Firms for Study

Thirty-five firms were selected for this study, based on their relative sizes in the North Central region in 1960.[2] Because most U.S. grain is produced in this region, these firms were also important nationally. Each accounted for five percent or more of regional volume in one or more of nine industry divisions (cereal, distilling, dry corn milling, feed manufacturing, flour milling, malting, merchandising, soybean processing, and wet corn milling). Two additional firms fell within this classification but were not included in the study because adequate size and growth data could not be obtained. These two firms accounted for 12 percent and five percent of their respective industries.

The firms studied did not, of course, occupy the same relative industry positions in 1960 that they had held in 1940, the beginning year of the study; they were the survivors who had either maintained or achieved dominance. Hence, it is likely that, as a group, they had grown faster and diversified somewhat more than average.

Size and Growth of 35 Large Grain Firms

Combined assets of the 35 firms rose from $1.4 billion in 1940 to $6.9 billion in 1963. About half of the increase represented real growth; the other half, inflation. Value of assets in real terms more than doubled during the period.

Direct external growth amounted to an estimated $1.257 billion between 1940 and 1963, or 22.7 percent of total growth. Relatively greater in the latter part of the period, it amounted to 28.8 percent of total growth between 1954 and 1963; 15.9 percent, between 1947 and 1954; and 18.3 percent, from 1940 to 1947.

Although numerous difficulties were encountered in measuring external growth precisely, the estimates are believed to be reasonably accurate for these firms.[3] However, the relative importance of external growth was probably somewhat understated for the following reasons: (1) Only direct external growth was measured. Growth that may have been generated from assets acquired earlier was classified as internal. (2) Price inflation of facilities acquired prior to the end of a period was also included as part of residual internal growth.[4] (3) Of the 641 acquisitions and 216 disposals recorded, the values of 120 acquisitions and 29 disposals could not be estimated. (4) Some transactions may have been overlooked. While possible overlooked disposals would partly compensate for missed acquisitions, the net effect of omissions would be toward underestimation of external growth. Taking these reasons into account, actual external growth may have approached one third of total growth, particularly in the latter part of the period.

---

[2] This was part of a North Central regional research project in grain marketing (NCM-30) [1, 2]. Relative sizes were derived from a 1960 NCM-30 survey [4].

[3] Data were obtained from a variety of sources, including Moody's Industrial Manual, corporate annual reports, previous research studies, Federal Trade Commission merger listings, financial periodicals, and trade journals. Estimates were made for missing data where estimating criteria were considered reliable, and the firms were then asked to make corrections and additions.

Firm size in 1963, measured by value of assets, ranged from slightly over $6 million for the smallest firm to nearly $700 million for the largest. The five largest firms, each with assets valued at more than one-half billion dollars, accounted for 45 percent of the total assets of all 35 firms in 1963.

Increasing Diversification

All but eight firms became more highly diversified between 1940 and 1963. Six firms entered new major Bureau of the Census Standard Industrial Classifications or alpha code industries. Twenty firms entered new two-digit industries, 26 entered new three-digit industries, and 27 firms entered new four-digit industries. Four of these each added more than 15 new four-digit industries to their lines of business.

A firm diversification index, developed to facilitate summarization of diversification tendencies, rose from an average of 1.61 for all 35 firms in 1940 to 3.21 in 1963, a gain of 1.60 (Table 1). Among the three groups—specialized, intermediate, and diversified—the 10 most diversified firms in 1963 were more diversified than others in 1940 and had become increasingly diversified relative to the other groups during the 1940-63 period. Firms in this group also were generally larger than firms in other groups. Thirteen firms remained highly specialized throughout the period.

Increasing diversification between 1940 and 1963 was associated with growth by merger or acquisition. An estimated 71 percent of external growth was considered either vertical or conglomerate rather than horizontal. Vertical growth backward toward sources of supply amounted to six percent; vertical growth forward, 17 percent. Conglomerate growth in areas unrelated to a firm's previous activities was estimated at 12 percent; in industries other than grain but somewhat related to a firm's previous nongrain activities, 34 percent; and in grain but unrelated to a firm's previous grain activities, 2 percent.

---

[4] An estimate based on constant value dollars indicated that 26.5 percent of asset growth between 1940 and 1963 was external, compared with 22.7 percent reported above. The external growth ratio in constant dollars was computed by multiplying the yearly ratio of external growth to total growth in current dollars for the 35 firms by the yearly change in constant dollar assets of these firms.

Table 1. **Diversification of 35 large grain firms, 1940 and 1963, grouped by degree of diversification in 1963**[a]

Degree of diversification	Number of firms	1940	1963	Change 1940–63
		average diversification index[b]		
Specialized	13	1.10	1.32	+ .22
Intermediate	12	1.57	2.99	+1.42
Diversified	10	2.33	5.93	+3.60
All firms	35	1.61	3.21	+1.60

[a] Major sources of empirical data were company annual reports, *Moody's Industrial Manual* for appropriate years, and the "1963–64 Plant and Product Directory" published by *Fortune.*

[b] The diversification index for each firm is the geometric mean of the number of U. S. Bureau of the Census, SIC, industries, one through four digits, in which the firm was engaged. For illustration, a hypothetical firm that processes soybeans (2092), produces livestock (0139), slaughters livestock (2011), processes meat (2013), tans leather (3111), and operates a meat market (5422) has a diversification index of 4.36 ($\sqrt[4]{3\cdot 4\cdot 5\cdot 6}$). This firm is in three SIC divisions (livestock production is in A; soybean processing, livestock slaughtering, meat processing, and leather tanning, in D; and meat retailing, in F). It is in four major groups (soybean processing, livestock slaughtering, and meat processing are in Major Group 20: Food and kindred products; livestock production, in Major Group 01; Commercial farms; leather tanning, in Major Group 31: Leather and leather products; and meat retailing, in Major Group 54: Retail trade). The firm operates in five three digit groups (livestock slaughtering and meat processing are in Meat Products Group 301; all others are in separate three digit groups). It is in six four-digit industries.

The geometric mean, in contrast with the simple average, was believed appropriate in reflecting the degree of diversification in a firm. Although its value is always smaller than the simple average, the geometric mean is relatively larger with more diverse activities, which are represented by the numbers on the left under the square root sign in the above example. The index treats both vertical and conglomerate integration as diversification.

Interrelations Among Size, Growth, and Diversification

Growth characteristics of the 35 firms for the 1954-63 period are shown in greater detail in Table 2. The more important associations were as follows:

(1) Overall rate of growth and percent of external growth were both inversely related to 1954 size.
(2) The larger firms were the more diversified.
(3) The most diversified firms grew most slowly between 1954 and 1963.
(4) Over one-third of the 1954-63 growth of the eleven most diversified firms in 1954 consisted of acquired facilities.
(5) Ten firms with the greatest increase in diversification between 1954 and 1963 were more diversified than other firms in 1954 and also averaged about three times as large.

Additional cross classification, based on both the 1954-63 period and the 1940-63 period, generally indicated that increasing diversification was positively associated with initial size, initial degree of diversification, and

Table 2. Assets, growth, external growth and diversification, 35 large grain firms by selected firm classification, 1954–63

Firms classified by	Assets per firm in 1954	Growth in assets 1954–63	External growth 1954–63	Diversification in 1954	Change in diversification 1954–63
	million dollars	percent		index

11 conglomerate	242.9	49.6	34.1	*4.29*	+1.28
Change in diversification, 1954–63					
14 least[a]	75.8	54.2	23.4	2.21	*− .03*
11 intermediate	70.5	71.2	36.4	2.25	*+ .45*
10 most	236.4	62.9	27.7	3.16	*+1.91*
All 35 firms	*122.0*	*62.4*	*28.8*	*2.49*	*+ .72*

[a] Includes 13 firms with no change in diversification between 1954 and 1963 and one firm with a decline.

external growth. A regression equation was estimated in order to determine the relative strength of these relationships, where

Y = Change in diversification index for each firm between 1940 and 1963,

X_1 = Dollar value of each firm's assets in 1940

X_2 = Diversification index for each firm in 1940, and

X_3 = Ratio of external growth to total growth for each firm during the 1940–63 period.

The results were as follows:

$$\begin{array}{l} Y = .167 + .011X_1^{*} + .131X_2 + .039X_3^{**} \\ \qquad\quad (.006) \qquad (.464) \qquad (.015) \end{array} \qquad R^2 = .31$$

(Standard errors in parentheses)

* Significant at 10 percent level

** Significant at 2 percent level

The results were consistent with tendencies observed earlier, but in this analysis the initial level of diversification was not strongly associated with further change in diversification. Similar associations were found for the 1954-63 period, although the ratio of explained to total variance was .24 rather than .31.

Conclusions and Implications

Growth by merger increased in relative importance for several large firms in the grain industry between 1940 and 1963. All but eight of the 35 firms studied became more highly diversified. Increasing diversification was associated positively with initial firm size and the relative importance of external growth. This tendency was consistent with the Federal Trade Commission's finding that large food manufacturing firms generally have turned increasingly to conglomerate mergers both within and outside the food industry, with a relative decline in horizontal mergers [7, p. 109].

The growing diversity within large firms seems likely to alter their behavior patterns and their competitive positions relative to other firms who deal or compete with them [3]. Just how the development eventually will influence overall economic performance and future industry structure is not altogether clear. Because of the size and pervasiveness of this structural change, further inquiry into causes and consequences of divesification tendencies may be increasingly useful both to business firms, in making management decisions, and to government agencies, in formulating and applying appropriate antitrust policies.

Federal Milk Marketing Order Provisions: Effects on Producer Prices and Intermarket Price Relationships*

George W. Ladd

Federal milk marketing orders contain formulas that determine prices received by farmers for milk delivered to bottlers. Different orders contain various combinations of provisions. Cross-section data were used to test the hypothesis that order prices are related to the provisions contained in orders. The hypothesis was accepted. Some 78 percent of the variance in prices is explained by two economic variables: distance of order market from Eau Claire, Wisconsin, and class I utilization ratio. Inclusion of dummy variables to allow for effects of order provisions increased the proportion of explained variance to 94 percent. Covariance analysis found no significant changes between years in the effects of order provisions on prices. Many possible combinations of provisions are not used in any order. Many of these combinations would provide unacceptable prices if they were used.

IN RECENT years the problem of maintaining proper milk price relationships among federal order fluid milk markets has become increasingly serious. This is mainly due to three factors:

(a) increase in the size and number of orders,
(b) improvements in the highway system and developments in long-distance hauling of bulk and of packaged milk, and
(c) growth in size of grocery chain stores and bottling plants.

The Federal Milk Order Study Committee was concerned with problems of intermarket relationships [2, pp. II-2-1 to II-2-15, II-4-1 to II-4-56, III-19 to III-23]. In 1955 the Agricultural Marketing Service published a study which dealt, in part, with intermarket price relationships [8]. Later, Babb [1] analyzed intermarket price relationships.

The objective of my study was to test hypotheses concerning effects of federal order provisions on relationships among prices in federal order markets. Dummy variables were used to study effects of order provisions. Covariance analysis was used to test for variation in the effects of these provisions.

The hypotheses tested will be presented after a brief discussion of federal order provisions; more complete descriptions can be found in publications of the U.S. Department of Agriculture [9, 10].

Federal Order Provisions

Most orders classify dairy products and milk into two classes. Fluid milk products—bottled or cartoned milk or cream, flavored milk drinks, etc.—are included in class I, and milk used in these products is class I milk. All other products are class II products; milk used in them is class II milk.

Minimum dealer prices for class II milk are determined by formulas based on prices of manufactured dairy products or on prices paid for milk used in such products. In some orders, minimum dealer prices for class I milk are determined by manufacturing milk formulas, which relate the class I price to prices of manufactured dairy products or the price of milk used in such products. In other orders, minimum dealer prices for class I milk are determined by economic formulas, which relate the class I price to selected economic factors such as prices and available supplies of feed, consumer income, and wholesale price index. In every order, the price for class I milk exceeds the price for class II milk.

Some orders contain a supply-demand adjuster provision. Under this provision the current class I utilization ratio (the proportion of milk received under the order used in class I products) is compared with a standard class I utilization ratio. If the current ratio is above the standard ratio, the minimum order price for class I milk is raised. If the current ratio is below the standard ratio, the minimum order price for class I milk is reduced.

Some orders contain a seasonal class I price differential provision, under which the minimum dealer price for class I milk varies seasonally.

After the minimum class prices to be paid by bottlers are established, the prices to farmers are computed. In an order having a market-wide pool, the total money value of all milk delivered to regulated bottlers by farmers is combined into one pool. The blend price is computed by dividing the value of this pool by the quantity of milk priced under the order. Each milk producer receives this blend price, minus his butterfat and location differential. In an individual-handler pool, a blend price is computed for each bottler separately. Each producer receives the blend price computed for his bottler minus butterfat and location differential.

Many orders contain one of two types of seasonal producer pricing provisions: the base-excess plan or the Louisville plan. Producer blend prices normally vary seasonally. These seasonal pricing provisions affect the seasonal variation in each producer's blend price.

Previous Studies

Babb [1] estimated equation (1) for each year 1947 through 1960.

$$Y_i = \beta_2 + \beta_3 X_{i3} + \beta_4 X_{i4} + \epsilon_i \tag{1}$$

where

Y_i = weighted average annual blend price, in dollars per cwt., for milk of 3.5 percent butterfat content in federal order market i.

$X_{i2} = 1$ for all federal order markets.

X_{i3} = distance of i-th federal order market from Eau Claire, Wisconsin, in miles.

X_{i4} = average annual class I utilization ratio in i-th federal order market. $0 \leq X_{i4} \leq 100$.

Since the order price for class II milk in Eau Claire, if Eau Claire had an order, would equal β_2, we expect β_2 to be positive. The area around Eau Claire is a potential source of grade A milk for any market. Since the cost of obtaining milk from the Eau Claire area increases with increasing distance from Eau Claire, we expect β_3 to be positive. Since class I price exceeds class II price, blend price rises as class I utilization ratio rises. Hence we expect β_4 to be positive. Babb's results agreed with expectations; he obtained positive significant values for b_2, b_3 and b_4 [1, p. 7]. (b_i represents the estimated value of β_i.) He found a positive correlation between b_2 and the level of support prices for dairy products and a negative correlation between b_3 and the level of support prices [1, pp. 2, 18]. He found that class I prices in northeastern markets were higher than predicted by (1), and he attributed this to the use of economic formulas in these markets [1, pp. 8–9]. Babb suggested [1, p. 7] that the type of pool affects blend price, but does so primarily by affecting class I utilization ratio. Many others have noted that markets with individual handler pools have higher class I utilization ratios and higher blend prices [8, p. 48; 5, pp. 4 and 7].

Williams et al. [11, pp. 40–43] noted that unlike behavior by supply-demand adjusters in different markets can affect intermarket price relationships. If these relationships are affected by differences in supply-demand adjusters, they may also be affected by the presence or absence of a supply-demand adjuster.

The Federal Milk Order Study Committee stated that the use of different seasonal pricing arrangements may cause short-run disparities in class I prices [2, pp. II-4-3]. This raises the question whether these seasonal pricing arrangements affect annual blend price relations. A finding that they do so would emphasize the importance of the question raised by Russell [7]. When he found that the seasonal pricing plan in the Boston federal order resulted in little variation in farmers' gross income from milk, even though seasonal production patterns varied substantially, he questioned the effectiveness of present seasonal pricing plans in stimulating more stable year-round production and proposed an alternative seasonal pricing plan.

These reports suggest that it will be useful to modify equation (1) to allow for effects of: (a) type of pool, (b) type of class I formula, (c) a supply-demand adjuster, (d) seasonal pricing plan, and (e) level of support prices for dairy products.

Procedure

Effect of federal order provisions

Variables X_{i5} through X_{i10} classify markets according to characteristics of their orders.

$X_{i5}=1$ if federal order in i-th market had a seasonal class I differential plan.
$=0$ otherwise
$X_{i6}=1$ if federal order in i-th market had a base-excess plan.
$=0$ otherwise
$X_{i7}=1$ if federal order in i-th market had a Louisville Plan.
$=0$ otherwise
$X_{i8}=1$ if federal order in i-th market had an individual handler pool.
$=0$ otherwise
$X_{i9}=1$ if federal order in i-th market contained an economic class I price formula
$=0$ otherwise
$X_{i10}=1$ if federal order in i-th market had a supply-demand adjuster.
$=0$ otherwise

Understanding the meaning of these variables is helped by referring to Table 1.[1] If the order in the i-th market contained a seasonal class I price differential, $X_{i5}=1$; if it contained an individual handler pool, $X_{i8}=1$; if it lacked a supply-demand adjuster, $X_{i10}=0$, etc. Class I orders contain a seasonal class I price differential, base-excess provisions, a market wide pool, a manufacturing milk class I price formula and a supply-demand adjuster. Orders in class II differ from these only in lacking a supply-demand adjuster. Each class of order represents a different combination of order provisions.

Let P_{i1} and P_{i2} represent class I and class II prices in the i-th market, and suppose they are related to the provisions in the federal order and to X_{i3}. Then we can write

$$P_{i1} = f_1(X_{i3}, X_{i5}, \cdots, X_{i10})$$
$$P_{i2} = f_2(X_{i3}, X_{i5}, \cdots, X_{i10})$$

and

$$(2) \qquad Y_i = [f_1X_{i4} + f_2(100 - X_{i4})]/100$$

Equation (2) will contain cross product terms of the form $X_{ij}X_{i4}$ if f_1 and f_2 are linear. Neither theory nor previous empirical work provides evidence as

---

[1] During 1962 there were no orders of certain classes. These empty classes are excluded from Table 1.

Agricultural Marketing Service, U.S. Department of Agriculture. 1959, 1960, 1961 and 1962. Milk Marketing Orders Division. *Federal Milk Order Market Statistics, Annual Summary for 1962*, Agricultural Marketing Service, U.S. Department of Agriculture. 1963.

to whether f_1 and f_2 may be linear or of some other functional form. To allow for non-linearities, I chose to estimate

$$\begin{aligned} Y_i &= \beta_2 + \beta_3 X_{i3} + \beta_4 X_{i4} + \cdots + \beta_{10} X_{i10} + \beta_{35} X_{i3} X_{i5} \\ &\quad + \beta_{45} X_{i4} X_{i5} + \beta_{36} X_{i3} X_{i6} + \cdots + \beta_{410} X_{i4} X_{i10} \\ &\quad + \beta_{56} X_{i5} X_{i6} + \beta_{57} X_{i5} X_{i7} + \cdots + \beta_{510} X_{i5} X_{i10} \\ &\quad + \beta_{67} X_{i6} X_{i7} + \cdots + \beta_{910} X_{i9} X_{i10} + \epsilon_i \\ &= \beta_2 + \sum_j \beta_j X_{ij} + \sum_k \sum_j \beta_{jk} X_{ij} X_{ik} + \epsilon_i \end{aligned} \tag{3}$$

The variable $X_{i6}X_{i7}$ was not computed since it is always zero by the definitions of X_{i6} and X_{i7}. $X_{i5}X_{i9} = X_{i9}$, showing that every order containing an economic class I price formula also contained a seasonal class I differential plan. The two variables $X_{i6}X_{i9}$ and $X_{i7}X_{i8}$ were zero for every observation; no order contained both a base-excess plan and economic class I price formula; and no order contained both a Louisville plan and an individual handler pool.

Equations (1) and (3) were estimated for each year 1959 through 1962. To find a function that was simpler than (3) that would adequately measure effects of federal order provisions, equations (4) and (5) also were estimated.

$$Y_i = \beta_2 + \beta_3 X_{i3} + \beta_4 X_{i4} + \cdots + \beta_{10} X_{i10} + \epsilon_i \tag{4}$$

$$\begin{aligned} Y_i &= \beta_2 + \beta_3 X_{i3} + \beta_4 X_{i4} + \cdots + \beta_{10} X_{i10} + \beta_{35} X_{i3} X_{i5} \\ &\quad + \beta_{45} X_{i4} X_{i5} + \beta_{36} X_{i3} X_{i6} + \cdots + \beta_{410} X_{i4} X_{i10} + \epsilon_i \end{aligned} \tag{5}$$

Implications for intermarket price relationships are derived from (3), (4), or (5). Consider any two markets, say, i and s. From (3),

$$Y_i - Y_s = \sum \beta_j (X_{ij} - X_{sj}) + \sum_k \sum_j \beta_{jk} (X_{ij} X_{ik} - X_{sj} X_{sk}) + \epsilon_i - \epsilon_s$$

expresses the difference between the blend prices as a function of difference in class I utilization ratios, difference in distance from Eau Claire, and differences in federal order provisions in the two markets. Letting $\Delta Y_i = Y_i - Y_s$ and $\Delta X_{ij} = X_{ij} - X_{sj}$, and assuming $\epsilon_i = \epsilon_s$,

$$\Delta Y_i = \sum \beta_j \Delta X_{ij} + \sum \sum \beta_{jk} (X_{ij} \Delta X_{ik} + X_{ik} \Delta X_{ij} - \Delta X_{ij} \Delta X_{ik}). \tag{6}$$

For $j, k \geq 5$, the only possible values of ΔX_{ij} are zero and plus or minus one; $\Delta X_{ij} = 1$ represents a change from an order lacking a specified provision to an order containing that provision. From (6) we obtain

$$\frac{\Delta Y_i}{\Delta X_{ij}} = \beta_j + \sum_k \beta_{jk} (X_{ik} - \Delta X_{ik}) \tag{7}$$

If we set the products $\Delta X_{ij} \Delta X_{ik} = 0$, (7) is replaced by

$$\frac{\Delta Y_i}{\Delta X_{ij}} = \beta_j + \sum_k \beta_{jk} X_{ik} \tag{8}$$

Effect of price support activities

The reasons for selecting the years 1959–62 are indicated in Table 2. U.S. Department of Agriculture purchases of milk solids rose substantially between 1959–60 and 1961–62. (There have also been considerable differences in more recent years in the level of support prices and in purchases of solids, but data for these years were not available at the time this study was begun.)

Table 2. Solids content of dairy products removed from the commercial market by programs of U.S. Department of Agriculture, as percentage of marketings; and announced support prices for manufacturing milk

Calendar year	Solids content of removals as percentage of		Support price per 100 pounds
	Milk fat marketings	Solids-not-fat marketings	dollars[a]
1959	2.9	9.1	3.06
1960	2.9	8.9	3.11
1961	7.0	11.2	3.36
1962	9.1	14.3	3.18

[a] Computed as weighted averages of support prices for marketing years beginning April 1.

Source: *Supplement for 1963–64 to Dairy Statistics through 1960,* USDA ERS Suppl. for 1963–64 to Stat. Bul. 303, 1965.

The hypothesis that intermarket price relationships are affected by support activities was tested by using covariance analysis to test the hypothesis that the values of the β's remained the same from year to year. The hypothesis that the intercept, β_2, and the slopes, β_3 to β_{910}, remained the same from year to year was tested by use of an F ratio, say $F(SL; INT)$. The hypothesis that the values of the slopes remained the same from year to year (intercepts unspecified) was tested by use of another F ratio, say $F(SL)$. These two F ratios are discussed by Johnston [6, pp. 136–138] and by Foote [3, pp. 180–183].

If $F\ (SL; INT)$ and $F(SL)$ are nonsignificant in comparisons of 1959 with 1960 and 1961 with 1962 but significant in comparisons of all four years, this will verify the hypothesis that changes in price support activities influence intermarket price relationships.

Hypotheses

Table 3 summarizes the hypotheses. Several come directly from the studies summarized previously. The fourth is included because one purpose of supply-demand adjusters is to make class I prices more responsive to variations in class I utilization ratio (X_{i4}); this would tend to make the blend price more responsive to X_{i4}. The fifth is included because it is expected that the amount by which blend price in an individual handler pool exceeds the blend price in a market wide pool is related to the class I utilization ratio. The last four are included because Williams [11] and the Federal Milk Order

[a] Hypotheses 6, 7, 8, 9, 10, 11 stated in terms of (8).

Study Committee [2] suggested that supply-demand adjusters and seasonal pricing plans may influence intermarket relationships, but they do not indicate the direction of the effects.

Results[2]

Covariance analyses

Results of $F(SL)$ and of $F(SL; INT)$ are summarized in Table 4.[3] The results accept the hypothesis that the slopes $\beta_3, \beta_4, \cdots, \beta_{910}$ were the same in each sample year and reject the hypothesis that the intercept had the same value each year. This means that variations in the dairy support price level affect blend price in all markets by the same amounts. Data for the four years can be pooled to obtain common estimates of the slopes. The results summarized in the rest of this paper were obtained using pooled data; pooling the data yielded 292 observations and from 260 to 289 degrees of freedom for t tests.

Table 4. Results of covariance analyses: significance or nonsignificance of F ratios for comparisons of results from various years

Years compared	$F(SL; INT)$	$F(SL)$
1959 and 1960	nonsignificant	nonsignificant
1961 and 1962	significant	nonsignificant
1959, 1960, 1961, and 1962	significant	nonsignificant

Statistics for equation (3.a)

The search for a simple relation between blend price and order provisions did not succeed, since equation (3) had a significantly lower residual sum of squares than (4) or (5) and all three had significantly lower residual sums of squares than (1). Intermarket price relationships are affected by federal order provisions and the effect of one type of provision is influenced by the presence or absence of other provisions.

Deleting from (3) the variables with nonsignificant coefficients and re-estimating the modified equation with pooled data yielded equation (3.a) in Table 5.

The procedure that was applied to equation (3) to obtain (8) can be applied to (3.a) to obtain values of $\Delta Y/\Delta X_j$. The results are:

$$(9) \quad \frac{\Delta Y}{\Delta X_3} = 10^{-3}(0.70 + 0.42X_5 - 0.21X_6 - 1.06X_7 + 0.16X_{10})$$

---

[2] Mileage data were obtained from *Standard Highway Mileage Guide*, New York, Rand McNally, 1961. Other data were obtained from sources cited in the footnote to Table 1.

[3] Throughout this paper, "highly significant" means significant at the 1 percent level; "significant" means significant at the 5 percent level.

[a] *** means highly significant; ** means significant.
[b] $j \cdot k$ means $X_{ij}X_{ik}$; for example 3·5 means $X_{i3}X_{i5}$.

$$\frac{\Delta Y}{\Delta X_4} = 10^{-2}(2.55 - 1.47X_5 + 0.93X_6 - 0.92X_7 + 1.02X_8 + 4.60X_9 - 0.44X_{10}) \tag{10}$$

$$\frac{\Delta Y}{\Delta X_5} = 10^{-2}(67.04 + 0.042X_3 - 1.47X_4 - 34.50X_7 + 23.49X_8 + 24.97X_{10}) \tag{11}$$

$$\frac{\Delta Y}{\Delta X_6} = 10^{-2}(-46.88 - 0.021X_3 + 0.93X_4 - 26.86X_8 - 9.25X_{10}) \tag{12}$$

$$\frac{\Delta Y}{\Delta X_7} = 10^{-1}(11.06 - 0.011X_3 - 0.092X_4 - 3.45X_5 + 7.09X_9 + 3.35X_{10}) \tag{13}$$

$$(14)\quad \frac{\Delta Y}{\Delta X_8} = 10^{-1}(-9.31 + 0.10X_4 + 2.35X_5 - 2.69X_6 - 4.00X_9)$$

$$(15)\quad \frac{\Delta Y}{\Delta X_9} = -3.74 + 0.046X_4 + 0.71X_7 - 0.40X_8 + 0.82X_{10}$$

$$(16)\quad \frac{\Delta Y}{\Delta X_{10}} = 10^{-2}(0.016X_3 - 0.44X_4 + 24.97X_5 - 9.25X_6 + 33.47X_7 + 81.97X_9)$$

$\Delta Y/\Delta X_j$ measures the difference between the blend prices in two orders that are alike, except that the value of X_j for one order is one unit greater than the value of X_j for the other order. For example, suppose two markets have the same class I utilization ratio, are located the same distance from Eau Claire and are alike in all other order provisions, but order i has an individual handler pool and order s has a market wide pool. Then $X_{i8}=1$, $X_{s8}=0$, $\Delta X_8=X_{i8}-X_{s8}=1$ and $\Delta Y/\Delta X_8=\Delta Y=Y_i-Y_s$. From (14) we see that the difference between the blend prices in these two orders (ΔY) depends upon their common class I utilization ratio (X_4), whether they have a seasonal class I price differential (X_5), a base excess plan (X_6), or an economic class I price formula (X_9). Suppose both markets have a seasonal class I price differential ($X_5=1$), a base excess plan ($X_6=1$) and a manufacturing milk class I price formula ($X_9=0$). Then $Y_i-Y_s=10^{-1}\ (-9.31+0.1X_4+2.35-2.69)=-0.965-0.010X_4$. If neither has a base excess plan, but both have seasonal class I price differentials and manufacturing milk class I price formulas, $Y_i-Y_s=10^{-1}\ (-9.31+0.10X_4+2.35)=-0.696+0.010X_4$.

Estimated blend prices

Estimated prices and values of (9) and (10), computed from (3.a), are shown in Table 6 for the nonempty classes or orders. Some classes or orders are consistently high priced and others are consistently low priced. Classes 11, 17, 19, 23, 26, 33, 34 and 42 are among the 6 highest priced classes in 3 or more of the 6 columns. Classes 5, 9, 18, 25, 41 and 46 are among the 6 lowest priced classes in 3 or more of the 6 columns.

Tests of hypotheses

Hypotheses 1 to 3.—Hypotheses 1a, 1b, 2a and 3 are accepted. These hypotheses are: (1a) Eau Claire class II price is positive; (1b) β_2 is positively correlated with support price, (2a) blend price is positively related to distance from Eau Claire; and (3) blend price is positively correlated with class I utilization ratio. Hypothesis 2b (β_3 negatively correlated with support price) is rejected.

Hypotheses 4 and 5.—Hypothesis 4, which states that the presence of a

supply-demand adjuster makes blend price more responsive to class I utilization ratio, is rejected. A possible explanation for the negative value of b_{410} relates to the downward trend in X_4 most markets have experienced. Writing $\Delta Y/\Delta X_4 = .026 - .004X_{10} + \cdots$, we see that blend price is reduced less for a given decrease in X_4 if the market has a supply-demand adjuster. Supply-demand adjusters have cushioned the price depressing effects of decreases in X_4. This supports the position of the Federal Milk Order Study Committee: "At best, experience with these adjusters as they have been administered has been that. . . they have not served as effective tools for reducing persistently excessive supplies" [2, pp. II-1-13 to II-1-14].

Hypothesis 5 is accepted: $b_{48} > 0$. $\Delta Y/\Delta X_4$ is 1.02 cents greater if the two markets compared have individual handler pools than if they have market wide pools. $\Delta Y/\Delta X_8$ is 10.2 cents greater if the two markets have 90 percent class I utilization ratios than if they have 80 percent class I utilization ratios.

Hypothesis 6.—This hypothesis states that orders with individual handler pools have higher blend prices than orders with market wide pools. The results confirm this hypothesis for some situations and reject it for others. The maximum value of $\Delta Y/\Delta X_8$ is $0.010X_4 - 0.696$, which is positive if $X_4 < 69.6$. The minimum value of $\Delta Y/\Delta X_8$ is $.010X_4 - 162.7$, which is negative for every value of X_4.

Existing orders with individual handler pools do have high blend prices on

$\Delta Y/\Delta X_9 > 0$ if $X_4 > 63.5$. Six of the 8 markets containing economic class I formulas in 1962 had values of X_4 exceeding 63.5. If orders with economic class I formulas lacked supply-demand adjusters, $\Delta Y/\Delta X_9 = -3.74 + 0.046X_4$. This is positive only if $X_4 > 81.3$. None of the markets containing economic class I formulas in 1962 had values of X_4 exceeding 81.3. The fact that existing orders with economic class I formulas tend to have high blend prices is due to the kind of class I formula they contain and to the presence of supply-demand adjusters in these orders.

Orders with economic class I formulas are not necessarily high priced orders. Of the 26 "low price classes" in Table 6 Extended, 13 have economic class I price formulas and 13 have manufacturing milk formulas. Of the 13 with economic class I formulas, all are empty; of the 13 with manufacturing milk formulas, only 2 are empty.

The positive sign on b_{49} may reflect supply conditions in the east and northeast, where markets with economic class I price formulas are located. Farmers in these areas generally have fewer good alternatives to dairying than do farmers in other areas. This tends to make supply less price-elastic. As a result, larger variations in price are needed to induce given variations in supply.

If we accept the positive signs of b_{49} and b_{910}, the sign of b_9 has to be negative to avoid unreasonable blend price differences. Suppose $b_9 \geq 0$ and $X_4 = 75$ (about the national average in 1962). Then $\Delta Y/\Delta X_9 = b_9 + \$4.27$. If b_9 were non-negative, a class I utilization ratio of 75 would result in a blend price that was at least \$4.27 higher if the order contained an economic formula than if it contained a manufacturing milk formula. With $b_9 = -\$3.74$ and $X_4 = 70$, $\Delta Y/\Delta X_9 = \$0.53$.

Hypotheses 8, 9, and 10.—These hypotheses state that blend prices are related to seasonal pricing plans. The results confirm these hypotheses for most situations. $\Delta Y/\Delta X_5$, $\Delta Y/\Delta X_6$, and $\Delta Y/\Delta X_7$ may be negative or positive. The use of different seasonal pricing arrangements does affect annual blend price relations. The effect of each one of the seasonal pricing plans on blend price is influenced by X_3, X_4, and X_{10}.

Hypothesis 11.—This hypothesis states that the presence of a supply-demand adjuster affects blend price. $\Delta Y/\Delta X_{10}$ is positive in some situations and negative in others. Some effects of supply-demand adjusters have already been mentioned in discussions of hypotheses 4 and 7.

Williams et al. [11] showed how the effects of seasonal price plans and of supply-demand adjusters may reinforce or offset each other. The coefficients of X_5, X_6 and X_7 in (16) also show this. For example, if $X_5 = X_6 = X_7 = X_9 = 0$, then $\Delta Y/\Delta X_{10} = 0.00016X_3 - 0.0044X_4$; if $X_5 = 1$ and $X_6 = X_7 = X_9 = 0$, then $\Delta Y/\Delta X_{10} = 0.00016X_3 - 0.0044X_4 + 0.25$; if $X_5 = X_7 = 1$ and $X_6 = X_9 = 0$, then $\Delta Y/\Delta X_{10} = 0.00016X_3 - 0.0044X_4 + 0.58$.

Hypotheses 6 to 11 could be tested by using the procedure discussed by

Fuller [4] to compare each $\Delta Y/\Delta X_j$ with its standard error. This was not done because of the expense. Even if we restricted X_3 to 4 possible values and X_4 to 3 possible values, there would be a total of 560 values of $\Delta Y/\Delta X_j$ to compute, as well as 560 different variances. However, this procedure was applied to a simpler equation than (3.a). Almost all values of $\Delta Y/\Delta X_j$ were substantially greater in absolute value than their standard errors, indicating rejection of the hypotheses $\Delta Y/\Delta X_j = 0$.

Empty classes

Of the 48 possible classes of orders, 30 are empty. Results from (3.a) show that many are empty because their particular combinations of order provisions provide unreasonable results in the form of: (a) unduly high blend prices, (b) unduly low blend prices, (c) undue sensitivity to variation in X_4, or (d) inappropriate effects of variations in X_3.

As explained, Table 6 Extended is obtained from Table 6 by filling in all columns for all classes of orders, including the empty classes. Let U_i, U_j, U_k, $\cdots$, identify empty classes. $U_i \leq 48$ and U_i is a number not appearing in column 1 of Table 6; U_j, U_k, $\cdots$ are similarly described. For example, $U_i = 3$ identifies order class 3, which is empty. Let C identify one of the columns 2 through 7 of Table 6 and Table 6 Extended. C = 5 identifies column 5. The lowest and highest values of $\hat{Y}$ in columns 2–7 of Table 6 are:

Column 2: \$2.72 and \$4.35
Column 3: \$3.23 and \$4.44
Column 4: \$3.47 and \$5.15
Column 5: \$3.55 and \$5.65
Column 6: \$3.80 and \$5.74
Column 7: \$3.96 and \$6.57

In the following, the expression "Classes U_i and U_j are P percent low priced in column C" means that values of $\hat{Y}$ for classes U_i and U_j in column C of Table 6 Extended are P percent or more below the smallest value of $\hat{Y}$ in column C of Table 6. Similar expressions are interpreted similarly. For example, "Classes 4 and 7 are 10 percent low priced in column 2" means that the values of $\hat{Y}$ for order classes 4 and 7 in column 2 of Table 6 Extended are 10 percent or more below \$2.72.

The emptiness of classes 4, 7, 8, 20, 24, 31, 32, 47, and 48 is explained by (b) and (c). These classes are 10 percent low priced in columns 2 and 3. The values of $\Delta Y/\Delta X_4$ for these empty classes range from 5.7 cents to 9.1 cents; all are larger than all but one of the values in column 9 of Table 6.

The emptiness of classes 36 and 40 is explained by (b), (c), and (d). Class 36 is 8 percent low priced in column 4; class 40 is 12 percent low priced in column 3. These classes have large values of $\Delta Y/\Delta X_4$. They have negative values of $\Delta Y/\Delta X_3$, indicating there would be a tendency for blend price to decline with increasing distance from Eau Claire for these classes.

The emptiness of classes 35 and 39 is explained by (a), (c), and (d). Class 35 is 7 percent high priced in columns 2, 5, and 6. Class 39 is 5 percent high priced in column 6. These two classes also have high values of $\Delta Y/\Delta X_4$ and negative values of $\Delta Y/\Delta X_3$.

The emptiness of class 38 is due to (b) and (d). This class is 8 percent low priced in column 4 and has a negative value of $\Delta Y/\Delta X_3$.

Classes 3, 15, 16, 27 and 43 may be empty because of their large values of $\Delta Y/\Delta X_4$: from 5.3 cents to 7.6 cents. $\Delta Y/\Delta X_3$ was slightly negative for each class from 33 to 40. All of these classes except 33 and 34 were empty. All markets in class 33 were between 600 and 630 miles from Eau Claire, and all markets in class 34 were between 350 and 510 miles from Eau Claire.

I hypothesize that these findings on empty classes reflect the operations of the Agricultural Marketing Service, Dairy Division, which had the responsibility of administering orders. Through experimentation with various combinations of provisions, they found that certain combinations would give undesirable or unacceptable results if used. Consequently, the Dairy Division issued no orders containing these particular combinations; or else it had issued such orders and modified them prior to 1962.

Offsetting and reinforcing provisions

From comparisons of signs of coefficients in (11) through (16), it can be seen that different provisions may reinforce or offset each other. For example, if $X_3=1{,}000$, $X_4=70$, $X_8=X_{10}=1$ and $X_7=0$, then $\Delta Y/\Delta X_5=44$ cents, but $\Delta Y/\Delta X_6=-39$ cents; also $\Delta Y/\Delta X_5+\Delta Y/\Delta X_6=5$ cents and $\Delta Y/\Delta X_5-\Delta Y/\Delta X_6=83$ cents. The effect of having a seasonal class I differential plan can be largely offset by having a base-excess plan. The effect of a seasonal class I price differential is enhanced by the absence of a base-excess plan. If $X_3=1{,}000$, $X_4=70$, $X_5=X_6=X_9=1$ and $X_7=0$, then $\Delta Y/\Delta X_8=-97$ cents, but $\Delta Y/\Delta X_{10}=83$ cents. The effect of having an individual handler pool is nearly offset by having a supply-demand adjuster.

Summary

Variations in the dairy support price level apparently affect blend prices in all markets by the same amount.

The relation of blend price to class I utilization ratio and distance from Eau Claire is affected by federal order provisions; the relation of blend price to one order provision is affected by other order provisions and by distance and class I utilization ratio.

Supply-demand adjusters have cushioned the blend price depressing effects of decreases in class I utilization ratio.

Existing orders having individual handler pools have high blend prices on the average. This is due to a combination of circumstances: (a) These orders have high class I utilization ratios; (b) they contain seasonal class I price differentials; (c) several combinations of other order provisions with individual handler pool provisions result in low blend prices. Few existing orders have these particular combinations of provisions.

Existing orders containing economic class I price formulas have high blend prices on the average. This is due to a combination of circumstances: (a) Most of these orders contain supply-demand adjusters; (b) several combinations of other provisions with economic price formulas result in low blend prices. No existing orders contain these particular combinations of provisions.

Effects of various seasonal pricing plans can reinforce or offset effects of other seasonal pricing plans and of supply-demand adjusters.

The results of this study point up the importance of the problem that concerned the Federal Milk Order Study Committee when it wrote: "The practice of varying the terms of the orders from market to market tends to magnify these problems of intermarket relationships" [5, p. II-4-1]. There is a conflict between the objective of maintaining reasonable intermarket relationships and the objective of adapting each order as closely as possible to the local market environment. The results of this study argue that the criteria used by the Dairy Division in formulating orders have been tied too closely to local market conditions and have not paid sufficient attention to intermarket relations.

The results raise the question: Since some provisions reinforce each other and others offset each other, are all the existing provisions needed?

Several combinations of provisions are unused because they provide unreasonable results: unduly low or high prices, oversensitivity to variations in class I utilization ratio, or decreases in blend price with increasing distance from Eau Claire.

Predicting Aggregate Milk Production: An Empirical Study

GLENN A. ZEPP AND ROBERT H. MCALEXANDER

There is a need for predictive and aggregate output response models suitable for answering questions about short-term changes in agricultural output. In this study, short-term milk output projections for Southeast Pennsylvania between 1961 and 1965 were derived with a linear programming, a recursive programming, and a regression model. The predictiveness of each model is evaluated by comparing its estimate of aggregate milk production with reported output for target years. Differences are expressed as percentage error from reported production.

PUBLIC policy makers, agricultural program administrators, and farm leaders often need knowledge of expected changes in agricultural production one or two years hence. Usually their inquiries will focus on what level of output will *most likely* be produced, and their interest will be areal, regional, or national in scope rather than limited to farm level. There is a need for predictive and aggregate output response models suitable for answering such questions about short-term changes in agricultural production.

Generally, empirical studies of agricultural output response can be categorized into one of two types: (1) historical or (2) synthetic. Nerlove and Bachman have reviewed the formal approaches and discussed some problems encountered in estimating farm output response [4]. Historical studies, mostly regression analysis, are based on examination of farmers' past responses to observable independent variables. Output projections from such an analysis are developed by extending past relationships into the future and are not founded on any well-defined theory of production.

Synthetic studies, primarily linear programming in recent years, are based on an economic analysis of the conditions underlying the production process. Such an analysis is more adaptable than the regression technique for studying the effects upon output of future changes in production conditions.

The linear programming approach gives profit-maximizing output estimates that usually are considerably greater than actual production. Recently, much effort has been devoted to improving the predictive quality of the linear programming model by introducing "flexibility" constraints to limit the yearly rate of adoption of new technology and change in enterprise combinations to those rates experienced in the past.[1] Such a

GLENN A. ZEPP *is an agricultural economist with the Farm Production Economics Division, Economic Research Service, USDA.* ROBERT H. MCALEXANDER *is professor of farm management at The Pennsylvania State University.*

model has aspects of both the historical and the synthetic approaches. The direction of change in output is determined through a synthetic-type model within the production theory framework. The extent of any change, however, is limited by flexibility constraints, thus reflecting the historical aspects of the model. The method has been termed recursive linear programming, hereafter called recursive programming. Some examples of the recursive programming technique are reported by several economists [1, 2, 3, 8].

Very few studies have compared the effectiveness of these different methods for estimating future agricultural production. One such study is reported by Schaller and Dean [8] in which regression and recursive programming estimates of cotton and alternative crops in Fresno County, California, were compared with reported production.

The purpose of this paper is to compare the predictive quality of a linear programming, a recursive programming, and a regression model in estimating short-term (1- to 5-year) changes in an area's milk production. Output estimates were derived with each type model and results compared with the milk production reported for the area.

Procedures

The analysis was based on the dairy industry for a 15-county area in southeastern Pennsylvania between 1960 and 1965. The area was selected to represent homogeneous farm and nonfarm economic opportunities. Resources available for dairying during 1960 were estimated from a 1961 survey of 1.5 percent of the commercial dairy farms in the area.[2] Prices and technical coefficients generally were chosen to represent the average for the study area. Some technical coefficients changed from year to year in the recursive programming analysis, reflecting the tendency for area crop and livestock production and fertilization and feeding rates to increase over time. The appropriate milk price was defined as the simple average of prices received in the study area during the two years immediately preceding production. Following are milk prices per hundredweight used in the analysis:[3]

Year	*Price*
1961	$5.00
1962	5.02
1963	4.93
1964	4.76
1965	4.82

---

mated year-by-year using production and price from year t to predict production for year $t + 1$.

[2] Commercial dairy farms were defined as those reporting milk sales during 1960.

[3] In projecting with the recursive programming model, a supply-demand analysis is usually needed in order to generate the milk price on which to estimate the following year's production. In this study, however, actual prices were used.

Sample farms were divided among 5 homogeneous resource groups so as to reduce aggregation bias in the linear programming output estimates.[4] The total of resources on all farms within each group was defined as a resource situation and was analyzed as one large operation. Programming-type milk output estimates for all the resources situations were summed and expanded by the reciprocal of the sampling rate to arrive at area estimates.

The linear programming estimate was a 5-year projection. Resources on sample farms during 1960 and prices and production technology representing 1965 were used in deriving linear programming estimates of 1965 milk production. The results were interpreted as the aggregate milk output, the enterprise combination, and resource-use changes that would occur within 5 years.

A series of 5 area milk output estimates for 1961 through 1965 were developed within the recursive programming model. Fixed resources for a particular year were defined as those resources employed during the previous year. The previous year's resources, in turn, consisted of its fixed resources adjusted for any change made through expansion or contraction activities within the programming analysis for that year. The initial resource situation was the same as that used in the linear programming model.

Regression estimates of area milk production for 1961 through 1965 were based on time-series data starting with 1950. One-year projections were developed for each of the 5 years, 1961 through 1965.[5] Then 2-year, and in turn, 3-, 4-, and 5-year projections were developed for each of the 5 test years. Regression parameters were revised for estimating each succeeding year's output to take advantage of the additional year of data in the time-series. For example, the 1-year projection of 1961 milk output was based on data for 1950 to 1960, while the 1962 1-year projection was based on 1950–1961 data. The 2-year projection of 1961 output was based on 1950 to 1960 data. The length of the time-series was extended year by year to 1962, 1963, and 1964, respectively, for the 1963, 1964, and 1965 1-year projections; and to 1961, 1962, and 1963, respectively, for the 1963, 1964, and 1965 2-year projections.

Estimates from each type model were evaluated by comparing them with reported production for their respective years. The difference between an estimate and reported production was expressed as percentage error from reported output.

---

[4] The logic of the classification procedure is presented by Sheehy and McAlexander [9]. The details of the procedure are presented in Zepp, [12, p. 203].

[5] For the regression model the length of projection indicates the time between the last observation in the time-series data and the target date.

Programming model

The linear programming model was intended to incorporate the most important economic, technological, and institutional forces influencing milk production in the study area.[6] Activity vectors represented the major livestock and field crops raised on southeastern Pennsylvania farms. Off-farm employment at $1.25 per hour, representing a movement of labor out of agriculture, also was included in the model as an alternative use for labor. A transfer activity permitted shifting dairy housing to use for beef, but beef housing could not be used for dairying. Other activities included milk sales, corn grain purchases, bedding material purchases, silo capacity expansion, and dairy housing capacity expansion.

Resource restraints in the linear programming model were for cropland, pastureland, silo capacity, family and regular hired labor (four seasons), expansion capital, bedding materials, and housing capacity for dairy, beef, hogs, and laying hens.[7] Rotation restraints were included to specify upper limits on the acreage of alfalfa and corn. Restraints also were included to keep the rate of grain feeding to dairy cattle within grain-to-milk ratios of 1:2 to 1:4. Other feeding constraints assured sufficient total disgestible nutrients for the livestock enterprises and limited per month forage consumption to 1/12 of the maximum permitted annual forage intake.

Some so-called "fixed resources"—cropland, pastureland, family and hired labor, silo capacity, and livestock housing facilities—could be adjusted within the linear programming framework. Farm use of family and hired labor could be decreased (increased) through off-farm employment (labor employment) vectors. Silo capacity and dairy housing expansion activities permitted increasing the existing supply of silage storage and dairy cattle housing. "Disposal" or "slack" activities permitted non-use of farm resources when it was profitable to do so. Some adjustment of farm resources also was made outside the linear programming framework as resources devoted to specialty crops in 1965, mainly vegetables, tobacco, and potatoes, were subtracted from the resource totals.

Flexibility constraints

In addition to the rows and columns of the linear programming matrix, the recursive programming model had six flexibility constraints limiting maximum year-to-year changes in resource use. These were intended to represent the many forces causing lags in resource adjustments, such as farmers' inability or unwillingness to make profitable changes because of risk, uncertainty, or personal preferences. The restraints were placed on the following activities: (1) off-farm employment of winter labor, (2) off-farm employment of spring labor, (3) off-farm employment of summer labor, (4) off-farm employment of fall labor, (5) expansion of dairy housing facilities, and (6) expansion of silo capacity. The magnitudes of these constraints were estimated as the average plus one standard deviation of percentage year-to-year changes in each resource during recent years.[8]

---

[6] Similar linear programming models have been used in the northeast dairy adjustments study and other regional adjustments studies [5].

[7] In the recursive programming model, flexibility constraints on silo capacity expansion and dairy housing expansion replaced the expansion capital constraint.

Regression model

The following regression model was used in developing area milk output estimates for 1961 through 1965:

$$y_{0,t} = y_{1,t} \cdot y_{2,t} \tag{1}$$

$$\Delta y_{1,t} = a_1 + b_1 X_{1,t} + b_2 X_{2,t} + e_{1,t} \tag{2}$$

$$\Delta y_{2,t} = a_2 + b_3 \Delta y_{1,t} + e_{2,t} \tag{3}$$

where

$y_{0,t}$ = area milk output in year t,
$y_{1,t}$ = number of cows milked in the study area during year t,
$\Delta y_{1,t} = y_{1,t+1} - y_{1,t}$,
$y_{2,t}$ = average milk production per cow in the study area during year t,
$\Delta y_{2,t} = y_{2,t+1} - y_{2,t}$,
$X_{1,t}$ = hourly return from farming to operator and family labor in year t divided by the industrial production worker weekly payroll index for year t,[9]
$X_{2,t}$ = average milk price received by farmers in the Philadelphia milk marketing areas during the previous 2 years, $X_{2,t} = (P_t + P_{t-1}) \div 2$
a_i = vertical axis intercept,
b_i = slope coefficients,
e_{it} = random error term.

The regression parameters were estimated using the two-stage least-squares technique.

---

[8] Flexibility constraints were estimated at 6 percent for off-farm employment, 4 percent for dairy housing expansion, and 9 percent for silo expansion.

[9] Return per hour from farming was for the Central Northeast dairy region [11]. Though the study area did not lie within the Central Northeast dairy region it was assumed that returns to operator and family labor would exhibit the same relationship in these 2 areas. Net returns for 1948 through 1956 were estimated by subtracting a capital charge, based on current interest rates, from farm income. For years 1957 through 1964, the interest rate used was 4.1 percent rather than the actual rates for those years. The industrial production worker weekly payroll index was compiled from reports of the U.S. Department of Labor [10, p, 460].

Results

The Pennsylvania Crop Reporting Service estimated area milk production for 1961 at 2,249.5 million pounds (Table 1). Production increased during 1962 and 1963, declined during 1964, and then increased slightly during 1965.

Table 1. Reported milk production and percent error of linear programming, recursive pogramming, and regression estimates, Southeastern Pennsylvania, 1961 through 1965

Year	Reported production[a]	Linear programming estimate	Recursive programming estimate	Regression estimates				
				One-year	Two-year	Three-year	Four-year	Five-year
	Million lbs.	*Percent error*	*Percent error*	*Percent error*	*Percent error*	*Percent error*	*Percent error*	*Percent error*
1961	2,249.5	—	−9.0	+ .4	−0.6	−4.3	−2.6	−2.1
1962	2,336.2	—	−1.9	−2.1	−1.6	−3.8	−6.7	−4.8
1963	2,376.7	—	+0.3	−0.1	−2.7	−2.2	−3.9	−8.1
1964	2,373.2	—	+4.2	+1.6	+1.3	−1.8	−1.2	−3.4
1965	2,375.5	+7.0	+7.5	+0.7	+2.8	+2.2	−1.3	−0.8
			(4.6)[b]	(1.0)	(1.8)	(2.9)	(3.1)	(3.8)

[a] Source: [6, 7].

[b] Figures in parenthesis are average absolute deviations.

The linear programming estimate of area milk production for 1965 was 2,540.9 million pounds, or 7 percent greater than reported output. Recursive programming estimates ranged from 2,046.4 million pounds for 1961, or 9 percent less than 1961 reported output, to 2,553.8 million pounds in 1965, or 7.5 percent more than 1965 reported production. The average deviation of estimate from actual production for the 5 years was 4.6 percent. Reported production declined slightly during 1964, whereas the recursive programming estimator predicted increases for every year.

The 1-year regression projections of area milk output ranged from a low of 2,259 million pounds in 1961, or about 0.4 percent more than reported production, to 2,411.8 million pounds in 1964, or 1.6 percent above 1964 output. Average deviations of estimates from reported production for the 5 years was about 1 percent. The largest error was 2.1 percent during 1962. The 1-year regression estimates indicated a decline in area milk output between 1964 and 1965 but did not predict the reported decline between 1963 and 1964.

Two-year regression projections ranged from 2,235.8 million pounds for 1961, or 0.6 percent less than reported output, to 2,441.8 million pounds in 1965, or 2.8 percent above reported production for that year. The average deviation of estimates from reported production over the 5 years was 1.8

percent and the largest error was 2.8 percent during 1965. The 2-year regression estimator did not predict the decline in reported area milk production between 1963 and 1964, but indicated increases each year from 1961 through 1965.

Average errors of estimate for the 3-, 4-, and 5-year projections were 2.9, 3.1, and 3.8 percent, respectively. Though the 1965 projections from these 3 estimators were close to reported output, the errors for some other years were high. The largest errors were 4.3, 6.7, and 8.1 percent, respectively, for the 3-, 4-, and 5-year projections.

The results seem to support the Schaller-Dean experience with predicting crop production [8]. As in this study, their regression models usually gave closer estimates of reported crop acreage and production (sometimes much closer) than the recursive programming model. Their recursive programming model tended to overestimate relatively small changes in acreage. They concluded that the recursive programming model may be more effective than regression when substantial changes in structure occur—such as the introduction of a new Government program.

Implications for Future Output Response Estimation

The programming-type models seem to be relatively poor estimators of reported production because they are basically normative tools, whereas regression is a predictive tool. Linear programming is a normative technique well suited for planning purposes, but its analysis is based on the optimization principle. For various reasons farmers in the aggregate do not optimize in the real world situation and linear programming estimates of production tend to be larger than actual output.

Recursive programming, as here defined, is an attempt to make a normative tool—that is, linear programming—more predictive by restricting changes in certain variables according to some criteria. In this study, historical magnitudes were used. This RP technique provides a predictive tool for use when structural changes would make regression results questionable.

Regression is a predictive tool and can reflect some of the forces influencing production that are difficult to take into account in the linear programming model. However, conditions underlying future production should generate similar relationships between variables as in the past if regression is to be a reliable predictive tool.

In this study, regression analysis seemed the most appropriate for projecting production variables. The two components of area milk production —number of cows milked, (y_1), and production per cow, (y_2)—continued trends established prior to the test years. The regression model was well suited to predict the changes occurring in these variables and hence gave close estimates of reported area production. The linear programming model overestimated actual production and the flexibility constraints tested in the recursive programming model did not improve the program-to March 31, for several thousand farm households[4] selected from Japan as a whole by stratified three-stage random sampling. One-person households were excluded from the survey.

Households were required to record income and expenditures (cash and in-kind) in the Family Account Book, which was verified by enumerators every month. In 1952, 1957, and 1962, part of the households in the survey were replaced, and the survey during these years was not based on identical families.[5]

In the time-series analysis the period dealt with is from 1951 to 1962, but the cross-section estimation covers only 1959–62 because cross-sectional data prior to 1959 were either unpublished or published without income information. The cross-sectional data represented single households classified by income into eight classes in 1959 and 1962 and seven in 1960 and 1961. The same information was also cross-classified by income and family size.

Since grouped data were used,[6] the number of households each year and in each income group was weighted in all equations.[7]

Cross-section Analysis

Engel curves are usually estimated by least-squares (LS) method, using measured income, Y, or total expenditure, C, as a regressor. According to the permanent income hypothesis, however, the LS estimates of the parameters of Engel curves using Y as an explanatory variable is biased downward. Also, Summers [10] has shown that the use of C as regressor in LS analysis leads to biased estimates, since individual expenditures are jointly determined with C.

On the basis of Summers' analysis, Liviatan [8] has developed a method to obtain consistent estimates of the parameters in the equation

---

[2] The four food items are cereals, potato-bean-vegetable-processed food, fish-meat-eggs-milk, and condiments-desserts-food prepared outside household. Housing consists of rent-repairs-improvements and furniture-utensils.

[3] The survey is conducted and published by the Agricultural Economic Bureau, Ministry of Agriculture and Forestry, Japan. Each year it is published in somewhat different form. The 1962 survey, for example, was published in 11 volumes in 1964. The 1962 data were taken from Volume 6: *Statistics of Farm Households Budgets.*

[4] Sample sizes of the time-series data are from 5,609 to 5,781 during 1951–1961, but only 2,830 for 1962.

[5] Changes in sampling procedures are not likely to produce much distortion for the time-series analysis; because of the large number of households in the survey, yearly averaged data of the sample would not be greatly affected by rotating part of the households. Although this is not the reinterview data of the panel survey, the data of time series of budgets used in this study are scarce in most cases.

[6] Data for individual households are not available. It can be shown that, although the variances of linear estimators become larger when grouped rather than individual data are used, unbiasedness is not affected by grouping.

[7] All equations were estimated by CDC 3600 computer program, "Weighting of Observations in Least Squares Problems" of Michigan State University.

$$\log X_i^* = \alpha_i + \beta_i \log C^*, \qquad (i = 1, \cdots, m), \tag{1}$$

where X_i^* is the systematic part of the expenditure on the ith item, X_i, and C^* the systematic part of C (i.e., permanent consumption). Liviatan has shown that a consistent estimate of β_i can be obtained by using Y as an instrumental variable (IV) for C in the double-logarithmic regression of X_i on C. This procedure is equivalent to using the equations

$$\begin{aligned} \log X_i &= a_{0i} + a_{1i} \log Y \qquad (i = 1, \cdots, m) \\ \log C &= a_0 + a_1 \log Y, \end{aligned} \tag{2}$$

since $B_i = \hat{a}_{1i}/\hat{a}_1$, where $\hat{a}_{1i}$ and $\hat{a}_1$ are LS estimates of a_{1i} and a_1 in (2), is the IV estimate of β_i [8]. Accepting Friedman's basic hypothesis [1] that the elasticity of permanent consumption with respect to permanent income is unity, B_i can be interpreted as the permanent income elasticity. Note that the empirical results show that the B_i are not much different from the corresponding LS estimates of expenditure elasticities (η_E's) using data classified by C.[8]

It should be noted that the IV method eliminates the simultaneous bias in a large sample only under a constant set of preferences. Bias may arise if family size, N, is not included in the equations, since it is the most important variable in a set of preferences. To eliminate the N effect, the average C and X_i are sometimes adjusted by family size elasticities (η_N's) when using data classified by Y alone, if an average N is available for each Y class. Nevertheless, this method is only approximate. More often the figures of Y, C, and X_i per household are converted to a per capita basis, hopefully to eliminate the N effect. However, the conversion to per capita figures is probably inferior to the adjustment by η_N's because the relationship between N and expenditure is not proportional. In our data classified by Y, there is not much difference in N in each group, so that biases in the LS estimates of income elasticities (η_Y's) using (2) for most commodities are very small.

If households are grouped by Y and, in each group, the average N is different, it may be impossible to estimate reliable η_Y and η_N if Y and N are correlated as they often are in budget surveys. Reliable estimates can be obtained from data cross-classified by Y and N.[9] In order to compare the IV estimates with the LS estimates from data cross-classified by Y and N, the parameters were estimated by simple regression with Y as the sole regressor and by multiple regression with Y and N as regressors.[10] All the equations were in double-logarithmic form. The results are not much different for the four years. The estimates in 1962 only are shown in Table 1.

---

[8] When grouped data are used, the regression of X_i on C should use the data classified by C. No farm budget data were classified by C. For the comparison of B_i and η_E, see [7]. Note also that, since in (2) the regressor is Y, the data grouped according to Y should be used when employing the IV method.

[9] See, e.g., [3] [7].

[10] The number of households in the cross-sectional equations for the four years 1959–1962 is 5,016, 5,352, 5,319, and 2,830 respectively.

Table 1. Demand relationships for basic living materials for farm households, 1962[a]

	Constant	Income elasticity	B_i	Family size elasticity	$\bar{R}^2(S)$
Simple regression					
Total expenditures	1.758 (.130)	.683 (.023)			.945 (.027)
Food	2.575 (.285)	.467 (.050)	.684		.625 (.059)
Cereals	2.965 (.493)	.333 (.086)	.487		.210 (.101)
Potato, bean, vegetables, and processed food	1.914 (.270)	.430 (.047)	.630		.611 (.056)
Fish, meat, eggs, and milk	.776 (.118)	.651 (.021)	.953		.950 (.024)
Condiments, desserts, and food prepared outside household	1.428 (.163)	.566 (.029)	.829		.883 (.034)
Housing	1.053 (.191)	.664 (.033)	.972		.884 (.039)
Rent, repairs, and improvements	1.313 (.198)	.553 (.035)	.809		.830 (.041)
Furniture and utensils	.290 (.274)[b]	.756 (.048)	1.106		.826 (.056)
Fuel and light	1.746 (.573)	.458 (.100)	.670		.276 (.118)
Clothing	−.586 (.186)	.925 (.033)	1.355		.939 (.038)
Multiple regression					
Total expenditures	1.928 (.065)	.631 (.012)		.177 (.014)	.987 (.013)
Food	2.993 (.056)	.339 (.010)		.434 (.012)	.986 (.011)
Cereals	3.696 (.065)	.108 (.012)		.759 (.014)	.987 (.013)
Potato, bean, vegetables, and processed food	2.300 (.082)	.312 (.015)		.401 (.018)	.965 (.017)
Fish, meat, eggs, and milk	.839 (.114)	.632 (.021)		.066 (.024)	.956 (.023)
Condiments, deserts, and food prepared outside household	1.624 (.101)	.506 (.018)		.203 (.021)	.957 (.020)
Housing	.926 (.167)	.703 (.032)		−.132 (.037)	.905 (.035)
Rent, repairs and improvements	1.186 (.185)	.591 (.034)		−.131 (.039)	.858 (.037)
Furniture and utensils	.170 (.271)[b]	.793 (.049)		−.124 (.058)[c]	.838 (.055)
Fuel and light	2.005 (.564)	.378 (.103)		.269 (.120)[c]	.329 (.114)
Clothing	−.465 (.173)	.888 (.032)		.126 (.037)	.950 (.035)

[a] Standard errors appear in the parentheses to the right of the coefficients.
[b] Denotes coefficients not significantly different from zero.
[c] Denotes coefficients significantly different from zero at 5% level.
All others (without notation) indicate coefficients significantly different from zero at 1% level.

Analysis of the estimates in 1962

All of the η_Y's in Table 1 are significantly positive at the .01 probability level. Of the 11 items, 4 show η_Y's below .5 and the rest show η_Y's between .5 and 1.0. The orders of magnitude of the η_Y's are generally as expected. It is natural that the η_Y is the lowest in cereals, and high in fish-meat-eggs-milk. The relatively high η_Y's in housing and clothing are in line with estimates in most previous studies.

Of course, the goodness of fit improves (i.e., $\bar{R}^2$ becomes larger) when a multiple regression is used. This is particularly evident for total food, cereals, and potato-bean-vegetables-processed food due to their large η_N's. If the η_N for a particular item is positive, its η_Y estimated by multiple regression is smaller than the corresponding figure estimated by using Y alone. The coefficient of the constant term, however, is larger than the corresponding coefficient obtained by a simple regression. When η_N is negative, the converse is true.

The η_Y's estimated by simple and multiple regressions are not much different in all items except cereals in consequence of its large η_N. The negative η_N's of housing and its components are due to the fact that as an increase in N makes the family relatively poorer, the family, after an increase in expenditures on relatively necessary goods such as food, cannot but spend less on housing. As the $\bar{R}^2$ for fuel-light is very low, the demand for the group does not seem to be determined by Y and N alone.

The B_i are considerably larger than their corresponding η_Y's. Since the B_i are consistent estimates of the "true" expenditure elasticities, β_i, and since they can be interpreted as the estimates of the permanent income elasticities, the η_Y's obtained by LS are underestimated.

Evidence from other budget studies

Nearly all other budget studies were based on non-farm data. Our results are not always directly comparable with those obtained by others because of different coverages, regression methods employed, classification of commodities, etc. Moreover, it would carry us too far to enter upon a detailed comparison.

Studies employing double-logarithmic equations were made by Tobin [11], Houthakker [3], and Yuize [12, 13, 14]. Using 1941 U. S. budget data for an analysis of the demand for food, Tobin [11] obtained $\eta_Y = .56$ and $\eta_N = .25$ for urban households, and $\eta_Y = .35$ for farm households.[11] In this international comparison of household expenditure patterns, Houthakker [3] used nearly all survey data conducted after World War II and a number of older surveys to estimate η_E's and η_N's for food, housing (including fuel-light), clothing, and miscellaneous items. The range of η_E's for the four items estimated from various surveys is fairly narrow but not equal; and the η_N's for food and miscellaneous items are similar, but those for clothing and housing irregular, among countries. On the basis of his estimates, Houthakker maintains that, if a country has no expenditure survey data available, it would not be too biased by assuming η_E at .6 for food, 1.2 for clothing, .8 for housing, and 1.6 for miscellaneous items; and η_N at .3 for food, zero for housing and clothing, and $-.4$ for miscellaneous items.

Comparing our multiple regression results with Houthakker's Table II (the results were estimated from 35 surveys data cross-classified by Y and N), we find that our small η_N's for housing and clothing are in accord with his and that our η_N for food is larger and η_Y's for food, housing[12] and clothing are smaller than almost all of his estimates. It should be noted that Houthakker used no farm data and used C rather than Y as the explanatory variable.[13] η_E should be greater than η_Y because the η_Y of C is less than one.

---

[11] The farm data were not classified according to N. The observations were adjusted by η_N of .25 to N 3.5 in each Y group.

[12] Several of Houthakker's η_E's are smaller than our η_Y. However, his housing includes fuel-light. Our weighted η_Y for housing and fuel-light is smaller than all of his η_E's.

Although there are a number of studies utilizing Japanese urban and farm survey data, most of them are unrelated to our analysis. The most comparable studies perhaps are those of Yuize [12, 13, 14] which are given in Table 2. The η_Y's in column (b) were estimated by using Y as the explanatory variable from per capita data grouped according to Y. These estimates are similar to our simple regression estimates, except for food. Our estimates are quite different from those in columns (a) and (c) for a few items. The η_N's in column (c) are generally too large; the magnitude of η_E's in columns (a) and (c) does not seem reasonable for some items. Yuize used C as the regressor to obtain η_E's in column (a) from per capita data classified by Y. This is inappropriate, as noted earlier. η_E's and η_N's in column (c) were obtained by using multiple regression with Y and N as regressors from data single classified by Y. As indicated before, the estimates thus obtained may not be reliable.

Table 2. **Demand elasticities for Japanese farm and urban worker households**

	(a) η_E for farm households in 1962	(b) η_Y for urban worker households in 1960	(c) Urban worker households in 1960	
			η_E	η_N
Food	.446	.299	.331	1.096
Rice	.252	.010	−.166	1.737
Vegetables	.322	.354	.671	−.057
Condiments	.196	.199	.221	1.049
Housing	.882	.795	1.333	−.718
Fuel-light	.259	.478	.581	.970
Clothing	1.337	.948	1.316	.215

Trends of income elasticities

In order to discover how the demand for basic living materials changed from 1959 to 1962, the data classified by income were used to estimate the regression coefficients by dummy variables. Assuming that the intercepts are the same but η_Y's are different during the period and taking 1959 as a base[14] (i.e., omitting the dummy variable of that year), the model is

---

[13] Of the 35 surveys in his Table II, only two surveys were classified by C. As noted earlier, when C is used as the regressor, data should be classified by C.

[14] Either one of the dummy variables or the over-all constant term must be omitted. Otherwise the parameters cannot be estimated because the matrix of the sum of squares and cross product is singular. It is more convenient to do statistical test by using the method of omitting one dummy variable.

$$\log X_i = a_i + b_{i0} \log Y + \sum_{j=2}^{4} b_{ij} D_j \log Y + W, \tag{3}$$

where W is a disturbance term, and

$$D_j = \begin{cases} 1 & \text{if observation is in the } j\text{th year,} \\ 0 & \text{otherwise.} \end{cases}$$

$j=2$ stands for 1960, 3 for 1961, and 4 for 1962. In (3), the over-all constant term, a_i, is actually the coefficient of the dummy variable omitted. The test of whether the jth year and 1959 have the same η_Y is a t-test.[15]

The results are presented in Table 3, which shows that η_Y of C changes little during the four years. The η_Y for total food decreases during the period except that the η_Y in 1961 is slightly smaller than that in 1960. While the η_Y's for condiments and for cereals as a whole, as well as its individual components, fall over time, those for food items with relatively high η_Y's such as fish, meat-milk-eggs, processed food, cakes-fruits-beverages, and food prepared outside the household increase considerably.

Table 3. Changes of income elasticities in 1960, 1961, and 1962 from the income elasticites in 1959[a]

	Constant	Year				$\bar{R}^2(S)$
		1959	1960	1961	1962

[a] The standard errors of estimates appear in the parentheses to the right of $\bar{R}^2$.
[b] Significantly different from 1959 at better than 1% level.
[c] Significantly different from 1959 at better than 5% level.
[d] Significantly different from 1959 at better than 10% level.
[e] Significantly different from 1959 at better than 20% level.
[f] Difference from 1959 is not significanlty different from zero.

---

[15] That is, apply a t-test to see if the estimate of b_{ij} is significantly different from zero.

The η_Y's for housing and fuel-light also increase during the period. The considerable increase in the η_Y for fuel-light over time might result from the availability of more electricity and gas in the rural area and the enlargement of housing space. The η_Y for clothing in 1959 and in the next few years does not differ significantly from zero, although the η_E in 1962 is larger than that in 1959 at the .2 level.

Time-series Analysis

The continuous cross-section surveys through time are very valuable for time-series analysis. In order to overcome the problem of multicollinearity and to obtain estimates consistent with both cross-section and time-series data, the method of combining both kinds of data has been widely employed. Briefly speaking, the method is to insert the η_Y or η_E estimated from cross-section data into the time-series equation. However, the validity of utilizing cross-section estimates jointly with time series is questionable because time-series and cross-section data are influenced by so many different factors.[16] Therefore, the ordinary LS also was used for comparing the estimates with those obtained by the combined technique.

The estimating equations

The "pure" time-series (without restriction) is:[17]

$$q_{ti} = A_i Y_t^{B_i} P_t^{C_{i1}} U_{ti}^{C_{i2}} V_t^{C_{i3}}, \tag{4}$$

where q_{ti} denotes per household demand for the ith commodity in year t; Y_t, per household current real income; P, own price, U_i, the price index of all commodities other than the ith commodity;[18] and V, a price index of related goods. The quantity variable of a given commodity is obtained by deflating expenditure on the commodity by the commodity price index.

Using the logarithmic form and treating quantity as a dependent variable,[19] the conditional regression can be written from (4) as:

$$\log q_{ti} - B_i \log Y_t = \log A_i + C_{i1} \log P_t + C_{i2} \log U_{ti} + C_{i3} \log V_t. \tag{5}$$

Not all the regressors in the equations entered computation at the same time; whenever V was included, U_i was dropped from the equation. One reason for doing so is to conserve degrees of freedom. Another reason is that U_i includes V which introduces multicollinearity if both are used as regressors.

---

[16] For a comprehensive discussion of the defects of the combined technique, see [5, 6].

[17] The equations including the preceding year's income were also estimated. However, the preceding year's η_Y's for almost all items are not significantly different from zero.

[18] U_i is converted from the general price index by removing the relative importance of the ith commodity. Thus, for the price index of each commodity, there is an "all other prices" index, which contains prices used in V.

[19] It is argued that whether quantity or price level should be used as a dependent variable in the demand relationship depends on a country's economic condition. Since Japan is not self-sufficient in food, a regression of quantity on price seems more suitable for the demand for food. Although the estimates by using price as a dependent variable can be regarded as "upper limits" to the "true" parameter, most of the elasticities obtained treating price as a dependent variable are so large that they may not be very useful as limits.

Results of the estimation

The estimates of (4) and (5) for seven items are set forth in Table 4. In the conditional regressions, the B_i were taken from the four years' average of the cross-sectional IV estimates. Because of the small number of observations, the Von Neumann-Hart test [2] was applied to test for autocorrelation in an observed sequence of random variables.

Estimation was also done for the equations where permanent income replaced measured income.[20] Although the results are not presented, it is worthwhile to note them. All the η_Y's estimated for various commodities are greater and the standard errors of the estimates smaller whenever permanent income replaced measured income. When both permanent and transitory incomes were used, the results show that, although permanent income is generally superior to transitory income in determining the demand for non-durable goods, transitory income appears more important than permanent income in explaining the demand for such durable goods as housing and clothing.[21] Despite the fact that the simplest method was used to derive permanent income and that a short time series was analyzed, the results appear to support Smith's [9] assertion that, while the permanent income hypothesis is verified with respect to non-durable goods, transitory income is an important variable in explaining the expenditures on durable goods.[22]

Table 4 indicates that:

(1) Except for meat-milk-eggs and fuel-light, the values of $\bar{R}^2$ fall considerably when the pure time-series regressions are replaced by the conditional regressions. This is especially marked for fish and clothing: the $\bar{R}^2$'s fall from very high to nearly zero.

(2) About one-half of the time-series η_Y's are larger than their corresponding cross-section estimates, especially those for meat-milk-eggs and housing. The time-series η_Y's for clothing are less than one-half of the cross-section estimate. One-half of the time-series η_Y's (i.e., for food, cereals, and fuel-light) are not significant at the .05 level, while all the corresponding cross-section η_Y's are significant at the same level.

(3) Only four of the 31 own-price elasticities have the wrong sign.

---

[20] An estimate of permanent income is constructed by Friedman's weighted moving average of measured income. For his lengthy discussion, see [1].

[21] The BLS does not consider clothing as a durable good because its normal lifetime is not long enough. In the Japanese income and expenditure survey, clothing is classified as durable good. Houthakker and Taylor [4] regard it as a durable, especially in view of their empirical results.

[22] This is consistent with Friedman's hypothesis, however, since durable goods are not consumed instantly and can be regarded as saving.

[a] Standard errors appear in parentheses to the right of the coefficients, all tests are two-tailed *t*-tests.
[b] Pure time-series equation (*P*) or conditional regression (*C*).
[c] Significantly different from zero at better than the 1 percent level.
[d] Significantly different from zero at better than the 5 percent level.
[e] Significantly different from zero at better than the 10 percent level.
[f] Significantly different from zero at better than the 20 percent level.
[g] Not significantly different from zero.
[h] The price elasticity of a particular commodity with respect to "all other prices."
[i] Evidence of serial correlation at the 5 percent level.

About two-thirds of the elasticities, particularly those for cereals and fish, are not significant at the .05 level. Although all the elasticities with respect to "all other prices" have the positive sign as expected, only one-third of them are significant at the .05 level. Results of the regressions for meat-milk-eggs indicate that both cereals and fish are substitutes to meat-milk-eggs, as one might expect, at the .01 significance level. It seems appropriate that housing and fuel-light are strong complements, as seen in the pure time-series results for housing. Nearly all the other elasticities with respect to related goods prices are insignificant at the .05 level.

(4) Of the 31 equations, four have positive serial correlation at the .05 level. A test of collinearity between income and prices shows that, of the 37 correlation coefficients, only one is positively and 20 are negatively significant at the .05 level. This is probably due to the fact that, although real income increased yearly, the price indexes of basic living material were quite stable or decreased slightly through time.

Concluding Remarks

Using cross-section data, the demand elasticities for various expenditure items were estimated by least-squares and instrumental variables. The least-squares income elasticity may be underestimated since it is substantially smaller than the corresponding instrumental variable estimate, which is a consistent estimate of the parameter. The income and family size elasticities tend to have an inverse relationship; the more "necessary" the good, the larger its family size elasticity.

In time-series analysis the ordinary least-squares and combined technique were used, the latter method with less success than the former. In many cases the income elasticities estimated from the time series were considerably different from the cross-section estimates.[23] Nearly one-half of the time-series elasticities were larger than their corresponding cross-section estimates. Despite the divergence between the income elasticities from cross section and from time series, the order of magnitude of the elasticities resulting from both analyses contained few surprises. The empirical results were consistent with the permanent income hypothesis.

Most of the own-price and all the "all other prices" elasticities carried plausible signs. Two-thirds of the elasticities, however, were not significant at the .05 level. Although nearly all the cross-elasticities with respect to the prices of related goods had the expected signs, most of them were insignificant at the .05 level.

Most of the cross-sectional estimates had magnitudes similar to those obtained by others. Prices are not as important as income in explaining Japanese consumption. The expenditure patterns of the Japanese farm households do not seem to be substantially different from those of the U. S. households.

---

[23] For the most detailed explanation of the reasons the estimates differ in the two different approaches, see [6].

Research Notes[*]

Financial Returns in Agriculture

Don Bostwick

Financial returns in agriculture are estimated in several ways, depending on the purpose of the estimate. When the purpose is to estimate the current financial condition of the farm firm as an operating business, one normally uses the estimated current market value of the resource as the base on which to calculate net worth. When the purpose is to estimate financial returns from proposed new money investments or from changes in past investments, one properly uses the current market value of the new resources in which one proposes to invest as a base on which opportunity rates of a future income stream may be estimated.

However, when the purpose is to estimate the rate of return earned by past money investments in resources of the farm firm, one cannot use current market value as a base. Nor can one use the opportunity cost method for this purpose, since there is no alternative to the investments made and no opportunity to alter them ex post facto.

This note deals with a system for calculating financial returns to past investments and gives an example of returns calculated under alternative assumptions of ownership and equity in the land resource.

Customarily, we state farm earnings as that positive or negative residual resulting from a subtraction of cash and noncash costs of the farming operation from the cash income produced by it. This procedure ignores noncash income that might result from the annual change in the inventory value of land, whereas such changes are included for buildings, stored seed and feed, and machinery and livestock. The annual increments of noncash income will be realized by the land owner when land ownership is transferred and will be taxable income at capital gains rates. This income is a value added to the investment by market appreciation—the obverse of invested money capital that is recovered in annual increments through depreciation.

---

[*] See Editors' comments in Communications section.

Don Bostwick *is an economist with the Economic Research Service, USDA.*

The market value of farmland in the United States has been increasing at an average annual rate of more than 8 percent since 1950, but this has not been reflected on the income side of most cost and return studies. Nevertheless, this is a source of income no less real than the growth in market value of industrial stocks—it is a return to the ownership of the land resource.

The general rule for calculating a rate of return on an investment is to divide the quantity earned in a given year by the amount invested. The quantity earned on an investment in farmland might have two components: (1) a noncash return to the investment, estimated by the mortgage rate of interest or some equivalent datum; (2) a noncash return to ownership of the resource, estimated by the annual increment in market value. The sum of these should be divided by the actual investment made—the quantity of money paid out by the owner in trade for his ownership—to obtain a more accurate rate of return.

Another potential source of error in many cost and return studies is the assumption that the typical farmer enjoys full equity in his farming resources. Equity is that portion of the value of a resource not pledged as security for a loan. If risk capital has been advanced by a lender, the financial return to the resource involved is split between the lender and the owner-investor. The former return is carried as a cash cost, the latter as a noncash cost, on the farmer's annual operating statement. There is no reason to suppose that the rate earned by the owner-investor is different from the contractual rate earned by the lender who shares the investment (though not the ownership). The dollars put in as equity capital by the owner-investor, and those put in as risk capital by the lender are identical and indistinguishable. These dollars must earn at the same rate, since there is no magic by which they may be differentiated after they are in the business.

The owner-investor who is heavily leveraged may include, as his, all noncash returns attributable to increased inventory value of the land resource, since he is the sole owner of that resource. He may show very small investment returns on this land resource, since his investment is small in proportion to the total. The heavily leveraged owner-investor will, of course, have a much smaller investment base on which to calculate his rate of return than the full equity owner-investor.

Table 1 illustrates the effect of these points on calculated rates of return. The full equity budget shown is taken from a current report on costs and returns of range beef ranches.[1] It is probably typical of the rancher who bought his resources in 1965 and has zero leverage. The part equity

Table 1. Costs and returns on a cattle ranch

Item	Full equity	Part equity
	dollars	
Investment:		
Land	1,528,837	550,381
Buildings, etc.	55,043	55,043
Machinery	8,491	8,491
Livestock	128,980	128,980
Total investment	1,721,351	742,895
Livestock income (cash)[a]	81,554	81,554
Land value increase (noncash)	—	61,153
Total income	81,554	142,707
Cash costs:[b]		
Operating	28,961	28,961
Interest (mortgage)	—	11,008
Total cash costs	28,961	39,969
Noncash costs:		
Depreciation	5,413	5,413
Operator and family labor	5,000	5,000
Interest on operating costs	1,014	1,014
Interest on investment	—	26,137
Total noncash costs	11,427	37,564
Net cash income[c]	52,593	41,585
Net ranch income	46,166[d]	65,174[e]
Return to capital and management	41,166[f]	72,512
Rate of return on investment[g]	2.39%	13.87%

[a] Income at 1956–1965 average prices.
[b] Prices at 1965 levels.
[c] Gross income less cash costs.
[d] Net cash income less noncash costs.
[e] Net cash income less noncash costs plus noncash income.
[f] Net ranch income less a charge for operator and family labor.
[g] Return to capital and management as a percentage of total investment.

Assumptions for the part equity budget:

1) Land was bought on mortgage in 1955, or 10 years prior to date of study. The current equity is 60 percent, and the mortgage carries a contractual interest rate of 5 percent.
2) There has been an increase in land values averaging 4 percent per year from 1955 to 1965, in the area where these ranch budgets are applicable.

budget shown is typical of the rancher who bought his resources in 1955 and in 1965 is 40 percent leveraged on the land resource.

If one wanted to use these data to calculate opportunity returns on a 1965 ranch land investment, one would start with the current land investment, as given in the full-equity budget, though perhaps with alternative leverage (equity) positions. One would then choose a probable annual rate of change in land value to project a series of budgets, including the capital gains component in returns. If one expects an annual rate of change that is linearly extrapolated on the past 10 years, the budget for 1975 might bear the same relationship to 1965 as the second budget in Table 1 does to the first.

One could complicate the analysis by including net cash returns after taxes each year and net of capital gains taxes when the land investment is liquidated *n* years hence. The after-tax effect would vary in proportion to the taxable income of the owner-investor in this ranch. But the tax shelter aspects of farmland investment and ownership are another story, and a more complicated one.

Financial returns in agriculture might look more competitive with those in other sectors if *all* returns and *all* costs were included in our budget studies. I suggest that very little additional effort would be required in our field studies to gather the data required for budgets like the part equity case above. This would seem to be more representative of financial returns than those we traditionally produce.

Did Futures Trading Influence Potato Prices?*

PETER M. EMERSON AND WILLIAM G. TOMEK

THIS NOTE has two distinct but complementary objectives: (1) to reconsider arguments on the relationship between the volume of trading in Maine potato futures contracts and changes in certain potato prices; (2) to illustrate two known but sometimes disregarded problems in economic research. The reconsideration, we believe, is justified by the numerous criticisms of commodity futures markets. This paper presents additional evidence with respect to an argument presented to the Congress in 1963 [see 4a].

Prior to 1950 there had been little trading in futures contracts for potatoes. In the crop years, 1951–1965, trading in Maine contracts increased substantially, but there was essentially no trading in Idaho contracts. Over the same time period, shipping point prices in Maine declined relative to those in Idaho (Table 1). Testifying before a Congressional subcommittee [4a, pp. 45f], an expert witness stated (a) that the price decline reduced returns to the Maine potato industry roughly $15 million a year, (b) "that futures trading played an important part, if not a dominant part," and (c) that change in "production was not the answer" to the price decline.

Table 1. Volume of trading in Maine potato futures contracts and ratio of Maine and Idaho shipping point prices for potatoes, 1946–1965

Crop years	Five-year averages	
	Trading volume	Maine-Idaho price ratio
	carlots	percent
1946–50	12,392	88
1951–55	105,778	75
1956–60	178,833	70
1961–65	316,783	70

---

[*] This paper reports a portion of a larger research project by Emerson [1]; for an earlier, broader analysis see Gray [2]. The authors wish to thank Roger W. Gray for his helpful comments on an earlier draft of this paper; we, of course, take full responsibility for the current content.

PETER M. EMERSON *is a Ph.D. student in agricultural economics at Purdue University;* WILLIAM G. TOMEK *is a visiting scholar, Food Research Institute, Stanford University* (1968–69).

Several price series are available to analyze potato prices in Maine and Idaho, two of which are examined in the following section. Each series leads to a different conclusion about relative price changes and the decline in returns to the Maine potato industry, thus illustrating the problem of data selection relative to a research objective. An analysis of Maine and Idaho potato prices for the crop years 1951–1965 (presented later in this discussion) suggests that, contrary to the testimony cited, changes in production do largely explain price variation through time. Furthermore, the net effect of futures trading on Maine prices, if any, appears to be positive, not negative. This illustrates that the net relationship, other variables taken into account, may differ from simple two variable relations and, hence, that reasoning from simple correlations can be fallacious.

Alternate Price Series

As with any commodity, there is no such thing as "the" price of potatoes. Shipping point prices were used in the critique presented to the Congress. These are prices at certain representative points in Maine and Idaho for U.S. No. 1 size A potatoes sold primarily for fresh (tablestock) purposes. Another, frequently used series is the season average price received by farmers, as reported by the Statistical Reporting Service (SRS) of the USDA, which measures average prices for sales for all purposes. These two price series for Maine and Idaho are summarized in Table 2.

Table 2. Shipping point and SRS season average prices for potatoes, Maine and Idaho, 1946–1965

Crop years	Five-year averages					
	Shipping point prices[a]			SRS season average prices[b]		
	Maine	Idaho	Ratio	Maine	Idaho	Ratio
	dollars per cwt		percent	dollars per cwt		percent
1946–50	2.40	2.73	88	1.94	1.74	111
1951–55	2.41	3.20	75	1.97	1.80	109
1956–60	1.89	2.70	70	1.63	1.52	107
1961–65	2.30	3.29	70	2.09	1.85	113

[a] U.S. No. 1, size A potatoes, mostly Katahdins in Maine and Russet Burbanks in Idaho.

[b] Weighted average price for all sales as reported by Statistical Reporting Service, USDA.

Relative prices as measured by the two series obviously have performed differently over the 1946–1965 period. The shipping point price series suggests that Maine prices have declined relative to Idaho prices; the SRS average price series suggests that they have not.

The explanation for the different conclusions lies in the definition of the two price measures. The SRS series is an average for all sales, both processing and fresh. Processing prices are usually somewhat below fresh use prices. In Idaho a relatively high and growing percent of the crop is sold for processing, whereas in Maine the emphasis is on tablestock sales. Thus, the average price for all sales is higher in Maine than in Idaho, and with the trend toward processing sales in Idaho, average prices in Maine have remained strong relative to those in Idaho.

Shipping point prices reflect mainly prices received by growers for sales in the fresh market. Idaho potatoes normally command a premium over Maine potatoes in the fresh market, which is reflected in this price series. The evidence also suggests that Maine shipping point prices did decline relative to those in Idaho, at least from the late 1940's until about 1961 or 1962.[1]

The analyst may legitimately wish to consider the influence of the volume of trading of futures contracts on the price of potatoes sold in the fresh market (i.e., shipping point prices). However, the correct measure of total revenue is total sales multiplied by the average price for all sales. Since this average has not declined either absolutely or relatively for Maine prices, it is difficult to conclude that the Maine potato industry is losing 15 million dollars a year because of trading in potato futures.

A Regression Analysis of Potato Prices

Specification of equations

Multiple regression analysis is used to estimate the net influence of certain variables on Maine and Idaho shipping point prices. The equations estimated specify price as a function of certain production and demand variables. The production variables measure local (state) production and production in the rest of the United States. Price and the production variables are expected, of course, to be inversely related.

Variables to capture shifting regional demands are more difficult to specify. Income is a typical demand shifter, but it is difficult to anticipate whether the coefficient would be negative or positive [see 3]. A linear trend variable also might be used to capture systematic shifts in demand, but trend is purely a proxy for other variables that may be influencing price. Population is taken into account by putting the variables on a per capita basis.

If the demand for Idaho potatoes for tablestock use is growing faster or declining slower than for Maine potatoes, as seems logical [1, pp.

---

[1] Idaho prices were significantly higher (by a *t*-test) than Maine prices for the crop years, 1946–1965. The ratio of Idaho to Maine prices, by 5-year periods, is given in Table 1. The absolute, average differences in prices for the same periods are 33, 79, 81, and 99 cents, respectively.

106–108], then the variables designed to capture shifts in demand would have larger positive or smaller negative coefficients in the Idaho equations.

The dependent variable for the Maine equations is the annual average shipping point prices (in Maine) per hundredweight for U.S. No. 1, size A Katahdins; for the Idaho equations, it is the annual average shipping point prices (in Idaho) per hundredweight for U.S. No. 1, size A Russet Burbanks. These prices are identical with those used in the 1963 testimony [4a] and hence permit direct appraisal of that testimony.

The independent variables include:
X_1 = Maine production, pounds per capita;
X_2 = Idaho production, pounds per capita;
X_3 = U.S. minus Maine production, pounds per capita;
X_4 = U.S. minus Idaho production, pounds per capita;
X_5 = personal disposable income in U.S. dollars per capita; and
X_6 = linear trend $(1, 2, \ldots, 15)$.

The estimates are based on 15 annual observations for the crop years 1951–1965.[2] The equations are linear in the observations. The coefficients are estimated by the method of least squares.

Results

Two equations for each state, which summarize the analysis, are presented in Table 3.[3] The table includes estimates of the regression coefficients, their standard errors, the Durbin-Watson statistic (d), the coefficient of multiple determination adjusted for degrees of freedom ($\bar{R}^2$), and the price flexibility coefficients.

Variation in prices in both states is clearly related to changes in per capita production, both locally and in other areas. Maine has a larger own-price flexibility coefficient than Idaho. Thus, a given percentage change in production in Maine has a larger influence on Maine price than the comparable change in Idaho.

Over the 15 years, 1951–1965, Idaho production per capita has trended upward, while Maine production per capita has shown no trend. Hence, the net effect of local production has been to depress Idaho prices. Maine prices, on the other hand, have fluctuated from year to year in response to

---

[2] The analysis begins with the 1951 crop year to avoid the price support period. The change in relative prices in the 1951–1965 period, however, was fairly small (see Table 2). This emphasizes Gray's point [2] that the removal of price supports was an important factor in the relative price change from the late 1940's to the early 1950's.

[3] These results are only a part of the equations estimated. Other geographic and seasonal breakdowns of production and other measures of demand changes were considered [see 1].

Table 3. Estimated regression equations for shipping point prices, Maine and Idaho potatoes, 1951–1965

Maine equations	Inter-cept	Independent variable[a]				$\bar{R}^2$	d	Price Flexibility[b]
		X_1	X_3	X_5	X_6			
1	12.001	−.166 (.068)	−.080 (.015)	.002 (.0008)		.71	2.05	−1.54
2	14.829	−.160 (.073)	−.081 (.016)		.052[c] (.032)	.66	1.79	−1.48
Idaho equations		Independent variable						
		X_2	X_4	X_5	X_6			
1	16.427	−.100 (.072)	−.129 (.041)	.002[c] (.002)		.73	2.39	− .74
2	19.599	−.126 (.090)	−.122 (.044)		.110[c] (.102)	.73	2.25	− .94

[a] See text for definition of variables and statistics.

[b] Price flexibility is computed at mean level of the dependent variable and X_1 or X_2.

[c] Coefficients not statistically different from zero at the 10 percent level of significance, using a one-tail test except for X_5 and X_6.

local production changes, but the overall effect has not been a downward trend.

The variables measuring external production (X_3 and X_4) are also important "explainers" of local prices. Partial r^2 coefficients for X_3 and X_4 are about twice those for X_1 and X_2. Price flexibility coefficients computed at the means indicate that a one percent change in producion outside the state results in a 4.5 percent change (in the opposite direction) in the state price, both for Maine and Idaho.

Over the 15 years, 1951–1965, per capita production outside of Idaho has remained about constant, while per capita production outside of Maine has increased. External production apparently has had no trend effect on Idaho prices but has resulted in a decline in Maine prices. In other words, a factor in the relative decline in Maine shipping point prices is the increase in production elsewhere.

The signs of the income and trend coefficients suggest that prices and "demand shifters" are positively related (net of the price-production relationships). In other words, after adjusting for changes in per capita production, the trend in prices is positive, whether measured by income or linear trend. However, the coefficients for these variables tend not to be statistically different from zero. There is some evidence[4] that the net positive changes in Idaho prices are larger for Maine. Hence, the influence of these variables, if any, is to cause a somewhat faster positive growth in Idaho prices. This, of course, is consistent with the idea of a relative decline in Maine prices.

---

[4] The trend coefficient in the Idaho equation is larger than that in the Maine equation. This plus estimates of coefficients of "demand shifters" in equations not presented in this paper are the basis of the evidence.

Incidentally, the pure empiricism of the analysis presented to the Congress can be carried one step further. It was based on the inverse correlation between volume of futures trading and relative price changes. The trend or income variables also have a simple inverse correlation with relative prices. The net relationship of trend and income with the price variables is positive. This suggests that if the volume of futures trading were used as a proxy for trend, the coefficient would be positive in the multiple regressions. Thus, carrying the empiricism to its logical conclusion, we could argue that the increased volume of futures trading "caused" higher potato prices in Maine, net of the influence of production.[5]

The results of the regression analysis are consistent with and lend support to two arguments by Gray [see 2 and 4b, pp. 58f]. He first emphasized the relatively greater impact of the price support program on Maine. It follows that the removal of the program is likely to have had a larger effect on Maine prices. The regressions indicate that a given change in local production has a greater influence on Maine price than on Idaho price. This suggests that Maine prices were more sensitive to a given transfer of production from government purchases to regular commercial channels.

Gray's analysis also indicates [4b, p. 67] that "buyers of (Maine) futures contracts have characteristically paid too high a price, representing excess demand for long positions in the futures market." Speculators were net losers [4b, p. 65], and hedgers, who are typically short, were the beneficiaries. Our analysis suggests that the net influence, if any, of futures trading on Maine prices would be positive.

In sum, changes in shipping point prices for potatoes in the 1951–1965 period are mainly related to changes in per capita production. This is in direct contrast to certain congressional testimony. The influence of "demand shifters" is apparently small but positive.

---

[5] Let X_7 = annual volume of trading in Maine potato futures in carlots (see Table I for average levels); then the estimated regression for Maine potatoes is

$$Y = 12.956 - \underset{(.065)}{.150X_1} - \underset{(.014)}{.067X_3} + \underset{(.000001)}{.000002X_7}, \text{ and } \bar{R}^2 = .74.$$

The coefficient for X_7 is small because the observations on X_7 are large relative to the price of potatoes. The *t*-ratio for this coefficient is 2.57; thus, the volume of trading variable has a statistically significant positive coefficient. The coefficient for X_7 retains its sign and magnitude even when X_5 and X_6 (income and trend) are added to the equation.

More on the Aggregation Problem: Some Suggestions

RICHARD H. DAY

MY ANALYSIS of the aggregation problem involved in developing linear programming models of representative farms [1] has received some attention—probably more than it deserves, in view of the rather discouraging implications it holds for the number of firms required for exact aggregation.[1] On the other hand, my suggestions [2] for circumventing the theoretical difficulties and practical costliness of the representative farm approach seem to have been overlooked. I therefore would like to take this opportunity to bring these suggestions to the attention of the readers of this journal, especially in the light of Marenco's and my respective reconsideration of the problem [this issue]. Specifically, I would like to suggest research in (1) the mathematical and behavioral analysis of "management leadership" and (2) development of research aids that would lower the cost of building and testing relatively large numbers of representative firm aggregate models.[2]

Management Leadership, Imitation, and the Number of Representative Firm Aggregates

In spite of the aggregation problem, there is indeed some evidence that at least crude aggregative fits can be obtained for agricultural data by the use of a single linear programming model for subaggregates, including all the farms in several counties, and of all ranges in size and resource variation [3]. This evidence led me to suggest that imitation of prominent producers' decisions by surrounding firms may lead to a considerable degree of proportional variation in farm *activities*, more than the l.p. behavior based on wide technical dissimilarities would predict. The idea is that individual farmers in a given small area tend to imitate "management leaders" or prominent producers and, as a consequence, behave as if they were much more homogeneous in input-output and resource structure than they really are.

Such behavior might have a well-defined basis in the theory of rational choice. This is because a decision maker who recognized his own limitations might, for quite rational reasons, imitate a neighbor in whose man-

---

[1] Cf. my comment on Marenco's paper, this issue.

[2] Terminology has never been standardized. I use the term "representative firm aggregate" to mean an aggregate of resources belonging to many different firms whose allocation is represented by a single microeconomic model of firms' decision making.

RICHARD H. DAY *is chairman of the Social Systems Research Institute, The University of Wisconsin.*

agerial ability he had greater confidence than in his own. In other words, he might make more money by doing a good job of applying another firm's solution than he would by attempting to find a solution optimal for his own technical conditions, simply because he is a good imitator but a poor optimizer.

There are at least two reasons why imitation of this kind would be distributed over time. First, it probably takes some time for a producer of modest managerial ability to be convinced of the improved efficiency of a neighbor's decision, and some decision makers will take longer to be convinced than others. Second, there is probably a conservative streak in many decision makers that leads them to be exceedingly cautious in departing from past decisions that have "worked." They tend to identify change with risk.

"Flexibility constraints" or "behavioral bounds" on individual activities or groups of activities are introduced into linear programming models to accommodate these two hypotheses. They allow for asymptotic convergence over time to the aggregate results that would be predicted without them. The l.p. model *without* flexibility constraints would be regarded as a solution that would be obtained under perfect certainty and by an aggregate of rational, consciously maximizing entrepreneurs, while the model *with* flexibility constraints gives the solution for an aggregate whose members move towards this hypothetical target at varying rates of speed.

There are other ways of modeling management leadership and imitation, and I would urge those wishing to contribute to the art of operational quantitative model building to push into this area.

Reducing the Cost of Model Building

The practical conclusion of the preceding remarks is that behavioral friction and imitation will justify the use of many fewer representative firm aggregates than would seem to be required from the parametric programming arguments. Even so, the number of subaggregates will be large, numbering at least in the hundreds for a country the size of the United States. Consequently, the microeconomic model building will be costly even when based on representative firm aggregates numbering a tiny fraction of the total number of firms whose aggregate behavior is of interest.

There is a limit to which modeling costs can be reduced by appeal to imitation, behavioral constraints, and the like. I would like to promote two means for further reducing at least the economist's part of these costs. First, I would like to see a comprehensive, living encyclopedia of agricultural technology and farm practices developed. This would provide economists (and other scientists) with a comprehensive and up-to-date source of basic input-output data from engineering sources, manufacturers' specifications, and sample survey data. A first edition could be compiled by carefully editing existing engineering journals, manufacturers' advertisements, and published survey results. It could be augmented with annual supplements, describing the latest innovations, and improved estimates of old technologies and practices, obtained from new surveys.

Second, I would like to propose the development of a data retrieval system for county agricultural data collected by the U.S.D.A. that would make aggregation and graphing of arbitrary commodities for arbitrary geographical aggregates over time inexpensive and timely. By informally and statistically comparing time paths of variables for alternative geographical aggregates, regions could be identified that exhibit similar behavior. This would help provide a guide to defining regional strata for representative firm analysis. A pilot system of this kind has been developed at the Social Systems Research Institute [4] and is now being extended.

Conclusions

Maximizing models modified to represent management leadership and imitation may be able to represent the behavior of much larger groups of firms than would seem to be suggested by an analysis of technical input-output coefficients and resource distribution. This hypothesis—if true—reduces the cost of model building by reducing the number of models that need to be built.

Even so, the number of representative firm subaggregates required for large agricultural regions will be quite large, and aids to reduce the cost of model building are clearly desirable. Two are suggested: (1) an annually updated encyclopedia of agricultural technology and farm practices and (2) a computer storage, retrieval, aggregation, and graphical display system. The former would reduce the cost of assembling input-output coefficients for large scale models. The latter would provide a means for establishing regional areas with similar commodity histories and hence with similar technical and behavioral structures.

Effect of a Health Hazard "Scare" on Consumer Demand[*]

JOSEPH D. BROWN

THE possibility of pesticide residue contaminations has become public knowledge in recent years. Such possible health hazards are new phenomena affecting the marketing of food. For example, when the Secretary of Health, Education, and Welfare announced on November 9, 1959, that cranberries may contain residues of a herbicide known as amino triazole, a major health hazard "scare" developed. This announcement received much consumer attention, and producers felt that the sale of cranberries from unsprayed bogs was hurt as a result [1]. Satisfactory documentation of the economic effects of this announcement is lacking, however.

This paper examines weekly household consumption of cranberries before (1957–58), during (1959), and after (1960–62) this pesticide "scare." Data were obtained from a panel of approximately 300 families in Atlanta, Georgia, who reported weekly food purchases for six years from 1957 through 1962. The analysis was based on weekly observations from households that purchased fresh and/or processed cranberries during the fourth quarter of each year.

The hypothesis is that consumer knowledge of possible pesticide contamination of cranberries would increase the price elasticity of demand. This hypothesis is based on two assumptions: (1) that the price elasticity of cranberries is similar to that of all fruit, and (2) that consumer knowledge of possible pesticide contamination may have the opposite effect of advertising on price elasticity.

Advertising tends to reduce the substitutability of a product through product differentiation. Advertising may also encourage more emotional buying and effort to consider substitutes [4]. Furthermore, ". . . advertisement may not only convince the new buyers that they should buy the product, but it may also convince the old buyers that the product is so good that they should not give up buying the same amount at much higher prices" [3]. Thus, advertising may decrease the price elasticity of demand. Conversely, known product contamination, or adverse advertising, may increase the elasticity.

Method

Variation in per capita purchases (Y) of fresh cranberries (pounds) and processed cranberries (ounces) was postulated to be dependent on

---

[*] Journal Series Paper No. 315, Georgia Agricultural Experiment Station.

JOSEPH D. BROWN *is associate professor of marketing at Ball State University.*

variation in the following independent variables, by week, during the fourth quarter of each year, 1957 through 1962:

$$Y = f(X_1, X_2, X_3)$$

where

X_1 = average price (cents per unit of weight),
X_2 = age of homemaker (1 = under 30, 2 = 31-45, 3 = 46-60, and 4 = over 60), and
X_3 = per capita income (dollars).

Thus, the derived demand elasticities are adjusted for the effects of age and income.

Linear and logarithmic least-squares equations were computed. The choice of the model was based upon the size of the coefficient of determination and the number of significant coefficients. Under these restrictions, the linear model was chosen for processed cranberries. Fresh cranberries were omitted from the analysis because the price coefficient was significant ($p \leq 0.05$) for only two of the six years.

Results

Forty-six percent of the households purchased processed cranberries during 1957-58 and 1960-62; 33 percent, in 1959. Per capita purchases of processed cranberries dropped 26 percent during 1959, compared with 1957–58, but regained the 1957–58 level during 1960–62. Retail prices, on the average, remained fairly constant.

Based on the linear regression equations for each year, the homemaker's age was positively ($p \leq 0.05$) related to per capita purchases of processed cranberries. Income was also positively ($p \leq 0.01$) related to per capita purchases, except during 1961. The quantity-price coefficient was significant ($p \leq 0.01$) in each of the six years. The demand elasticities for processed cranberries, computed at the mean values of these independent variables, were as follows:

1957, $\varepsilon = -0.87$	1960, $\varepsilon = -1.16$
1958, $\varepsilon = -0.93$	1961, $\varepsilon = -0.88$
1959, $\varepsilon = -0.93$	1962, $\varepsilon = -0.77$

To test the hypothesis of difference in these demand elasticities, an equation was estimated for the combined six years to test if one regression can be used for all observations, as follows:

$$\begin{aligned} Y = 7.754 &- \underset{(0.4166)}{4.5672X_1} + \underset{(0.1840)}{1.7631X_2} + \underset{(0.0001)}{0.0012X_3} \\ N = 1419 & \qquad R^2 = 0.203 \end{aligned}$$

Based on the computed F value, no significant differences existed among the six years. Thus, no statistical evidence exists to support the hypothesis of an increase in demand elasticity following a period of public knowledge of possible pesticide contamination.

The observations for 1959 and 1960 and for 1961 and 1962 were paired, since no significant difference existed between the regressions for each year within these two pairings. It was postulated that the observed decrease in demand elasticity from 1959–60 to 1961–62 was significant and might possibly be due to the increased advertising expenditures that occurred, at least in part, for the industry.[1] Following the same testing procedure used for the hypothesis of increased elasticity, it was found that no significant difference existed between the two regressions for the two periods. Thus, no statistical evidence exists to support this supposition about advertising expenditures.

Implications

The Food and Drug Administration has issued assurances about the safety of our food from pesticides. Their studies indicate residues "... are substantially below the limits set for acceptable daily intake by the World Health Organization and United Nations Committees" [2]. This record, however, does not prevent the occurrence of incidents similar to the 1959 cranberry pesticide "scare."

The 1959 incident appeared not to have had any significant affect on the elasticity of demand for processed cranberries among households in Atlanta, Georgia. The only apparent effects were temporary declines in the number of households purchasing processed cranberries and in per capita purchases among purchasing households. Advertising may be an effective tool to offset in part a change in demand elasticity resulting from a pesticide residue incident. This area warrants further research, particularly identification of socio-economic sub-groups who react either positively or negatively to various forms of advertising in relation to their levels of purchasing.

ECONOMETRICIANS AND THE DATA GAP: REPLY—COMMENT

Surely, most of us read this Journal for the best reasons—to see the results of research in areas other than our own and to learn of newly developed analytical tools or fresh applications of proven tools, thus keeping up with happenings in the profession; or perhaps just to learn from the free flow of critical ideas concerning each other's research efforts. For the interested but uninitiated, professional controversies can offer special opportunities for gaining insight into current problems. Such was my hope when reading the comments of Grove regarding the data gap and econometricians.

However, I must confess that I failed to find adequate reply from Scott and Heady to the major complaints of Grove. Let me be clear that I do not wish to enter into this debate as a participant, but as an observer interested in learning and in testing my assumed knowledge of the subject matter.

Grove's major observations seemed to be:

(1) That too many econometricians, especially the aspirant, have low quality thresholds when it comes to their model input data.

(2) That an example of this is found in the Scott-Heady study referred to, because

(a) data used legitimately to calculate certain depreciation values, and which were then allocated in a legitimate manner, were *conceptually* misused to generate input for the Scott-Heady model, and

(b) in the process of obtaining "satisfactory" results from the model, Scott and Heady violated a basic research principle—that of not fishing *a posteriori* for significant variables.

(3) That too many econometricians are unwilling to forsake quantity for quality in their model building.

The reader may wish to agree or disagree with the first and third complaints, which, after all, are generalizations. However, Scott and Heady might conceivably retort successfully to these charges and yet be guilty of complaint (2).

Their reply to (a) suggests a contest of professional credentials, both personal and with members of ERS. The reader is then referred to their Bulletin 545 for additional findings that presumably will clarify this whole matter. Grove's complaint (b) is turned against him in the form of a least-cost justification. However, it seems to me that if the complaint is correct, there could be no justification, even if resources for the model were *free*. Finally, it appears that Scott and Heady admit their data is erroneous (whether in accuracy or as used is not clear) but divert the reader's attention through the device of an irrelevant dilemma.

The reply may be personally gratifying to its authors, but it is not very satisfying to a reader who hopes to learn from the exchange between assumedly qualified individuals. Up to now, the exchange has been less than straightforward and, consequently, disappointing.

A WATER RESOURCE ECONOMIST LOOKS BACK AT A LAWYER

We stand condemned of failure to "eliminate legal constraints" to optimal utilization of water resources [3]. Although I am not sure whether most economists would feel insulted by or proud of this condemnation, I do believe that Levi has presented only a cursory view of the activities and motivations of many water resource economists. As a lawyer, he apparently has led a sheltered life, sheltered not only from the interdisciplinary realities of law making, but also from the supposedly objectionable[1] presence of an economist at every turn.

In the process of developing his condemnation, Levi makes the following observations, to which I shall respond in turn.

1. *Legal constraints on allocation make possible letter-perfect case studies, which can ultimately result in the creation of policy.*—The mere fact that an economist must deal with a common property resource and the associated tendencies for all forms of technological and pecuniary externalities, to say nothing of the ever-present necessity of struggling with the problem of interpersonal utility comparisons and the social welfare issues that are always present in an evaluation of water use alternatives, removes these studies from the "letter-perfect" category. What Levi is suggesting is that we can take these elements, along with the many facets of production and demand, label it all *ceteris paribus* and proceed to evaluate the isolated effects of certain legal constraints.

Assuming the existence of usable data, the quantification of these constraints still remains a herculean task, even with a host of simplifying assumptions. Without this data and the questionable legitimacy of the assumptions, the task facing a researcher of this common property resource may be more appropriately labelled hopeless than letter-perfect. To further compound this problem, all one needs to do is to ask two different lawyers for an opinion on a single legal point.

---

[1] To some administrators and lawmakers.

2. *Water resource economists have the opportunity to help shape society's future by developing new systems of water law based on economic theory.* —An economist making such a statement would be attacked as exceedingly naive. Indeed, there are presently several debates on the procedures used in certain aspects of water resource analysis, such as (1) measuring the demand for recreation, (2) the measurement of consumer surplus, (3) the quantification of externalities, (4) the appropriateness of micro-regional input-output models, (5) the adjustment of discount rates in benefit/cost analysis, and (6) the inclusion of regional secondary benefits.

There is no doubt that, in facing these problems, economists may be able to help shape society's future. However, it will not be by developing new systems of water law based on economic theory. There would be general agreement that economists must recognize institutional constraints in model building, especially if these constraints play a dominant role. We must therefore subsequently so phrase our conclusions that they may be of value to members of every associated discipline. Further, I agree with Levi's personal opinion that economists should be aggressive in communicating with lawyers, but I would add an equal responsibility for lawyers to seek out new knowledge from all disciplines related to the modification of old or the initiation of new precedent in water law.

The essential point here is that nothing is based on economic theory alone. Water resources especially represent an interdisciplinary management problem. Decisions must be based on a combination of technical, economic, social, and political considerations. If lawyers can specify those items of economic information they need, economists will respond, although this may be accompanied by a lecture on interpersonal comparisons and equity considerations.

3. *A review of the literature supports this.*—As Levi suggests, *selecting the proper forum* is crucial in communicating results of economic analysis to legislators (lawyers). He also suggests, and I agree, that journal articles are not appropriate as they are seldom read (or understood) by the right people. I am puzzled how, in light of these statements, he can then conclude that economists are failing to communicate by reviewing "the literature." They may in fact be using other, more direct channels to communicate information that is of value to legislators. The publish or perish syndrome has on the whole been admirably by-passed.

The legislative impact of the discussions at the turn of the decade cannot be truly measured. We can, however, look to the increasing role played by the water resource economists in the Natural Resource Economics Division of ERS, USDA, the Corps of Engineers, the Soil Conservation Service, the Water Resources Council, the Office of Water Resources Research, the Federal Water Pollution Control Administration, and numerous other Federal, State and regional bodies. Literally hundreds of economists in these agencies are directing their efforts toward the planning, development, and administration of water resources. For many of these men, their ultimate achievement is to see the fruits of their work published in the *Federal Register* or some equivalent state organ.

Levi would approve of this motivation, I am sure, yet he is apparently unaware of this group of economists, who certainly predominate among the total of all water resource economists, if only by their numbers alone. Even in academic circles, economists like Castle, Crutchfield, Wantrup, and Gardner have communicated quite successfully with lawyers such as Johnson, Trelease, Sato, and men in administrative positions ranging from Federal to local.

4. *Economists should turn their creative talents to developing innovative legislative mechanisms that approximate the results of the purely competitive market system and are palatable to legislators and other policy makers.* —The key word here is the adjective *legislative*. Economists have long been intrigued with mechanisms (viz., their interests in regional compacts, bribes, and charges, etc.). I submit however, that legislative mechanisms represent an area of mystique more germane to the political scientist or the practicing politician. It would be inefficient use of time and talents for an economist to try to operate as an amateur in this medium.

The appropriate sequence would include an exchange, in the legislator's language, between the economist and the legislator, including the essential recommendations for change. The legislator will then suggest what he believes to be the appropriate legislative mechanism. The economist may review these to ascertain whether they are capable of attaining the desired results. These suggestions will then be forwarded through the political process. At any point in this sequence, the concepts and/or their representative mechanism may be rejected. Once this has occurred, the economist can pursue the matter further only as a citizen crusader. In making this observation I am merely acknowledging that to be an economist one must pursue the science (art?) of economics. We can no more become lawyers and legislative mechanics to create the laws to regulate pollution than we can become the architects and engineers who design and build the treatment plants.[2] Although it may not be necessary to publish in order to avoid perishing as economists, it is necessary to limit one's activities if one is to avoid becoming a "jack of all trades, master of none." Those who have broadened their activities to the detriment of their economic "sophistication" are well aware of the professional degradation and often the financial sacrifice that may result.

5. *Eliminating this constraint will permit a movement toward the optimal point of production.*—Levi may be more appreciative of the difficulties involved when the errors in this statement are indicated.[3] First is the

---

[2] Further discussion on the role of the economist may be found in [1] and [2]. Levi's basic point seems to be an extension of what Breimyer labelled as one of the products of agricultural economics, "guidelines to the making of public policy" [1, p. 343]. If Castle has some objections to Breimyer [2, p. 813], I assume he will react quite strongly to Levi.

[3] The comments under this point were enhanced by a discussion with Frederick V. Waugh.

exclusive focusing on a firm while at the same time concluding that an increased benefit will result from *our water resources.*

At issue here is private versus public optimization. Removing a law that prohibits the disposal of effluent into a stream may allow a firm generating effluent to minimize cost while increasing both production and profits. From the firm's individual point of view, the absence of such a law creates optimum conditions. However, for many downstream users who need water of a certain quality for economic *and* social purposes, removal of this protective law may also remove a precondition to their optimal use of *our* resources.

In another example, a groundwater user may benefit from the cancellation of a restriction on withdrawal rates. As this resource is shared by others, this near term activity may have detrimental effects on productivity of all firms at some time in the future when the supply is depleted. In this example, even the individual firm in question may not be maximizing its discounted stream of earnings in the absence of the regulation on withdrawal rates.

Even with these considerations of the individual concern versus the public and the near term as opposed to the long run, we still have not faced the issues of equity and income redistribution. With all of these contingencies, it should be obvious that the elimination of a legal rule will permit true optimization only within a specific set of circumstances. With this in mind, it would be foolhardy to suggest that "they [economists] should reorient their research efforts and adopt as their mission not only the identification, but also the complete elimination of all legal constraints."

Concluding Comments

Despite the above comments, I find myself sympathetic to Levi's plea to water resource economists to become more aggressive in seeking the revision of the legal structure of water law based on the findings of economic analysis. However, his flattering but rather naive overstatements of the potential in this area does a disservice to economists, lawyers, legislators, and administrators who are diligently struggling with the manifold aspects of the problem. They should not be discredited because they have not (a) eliminated legal constraints and therefore optimized production, (b) developed new systems of water law based on economic theory and assisted by letter-perfect case studies, (c) developed appropriate legislative mechanisms, and (d) presented all this in lay terminology to lawyers, administrators, etc., while at the same time miraculously forcing these same lay writings into "the literature."

Given that the explicit statement of certain water laws permits a more effective venture into institutional economics, this may explain why in fact this is one area in economics where more planning, problem-oriented research is being conducted at all levels. Condemnation by certain economists who advocate more "sophisticated, basic" research is one matter, but criticism from lawyers at the other extreme could be unjustifiably demoralizing if left unchallenged.

EXACT AGGREGATION WITH LINEAR PROGRAMMING MODELS—A NOTE ON THE SUFFICIENT CONDITIONS PROPOSED BY R. H. DAY

Richard H. Day's 1963 article [1] on exact aggregation in linear programming models has now become an obligatory reference for research workers in the field of aggregate linear programming. Day presented sufficient conditions for using—without loss of precision—a single aggregate model to define the optimum combination of productive activities for a group of firms, rather than separate models for each firm.[1]

The aim of this note is to show how at least one of these conditions—required particularly for obtaining from the aggregate models unbiased results for the unknowns of the dual problem—is not necessary. More precisely, the condition in question is not an additional condition with respect to those remaining, in that it is always respected if the others are already respected. From a certain point of view, one can therefore say that the modification proposed here to Day's results is only formal. However, in addition to constituting a conceptual clarification, this modification could also have practical relevance for those who wish to make use of the conditions of Day in an empirical research work, thereby avoiding the useless control of a condition that necessarily holds.

Briefly, the results of Day may be summarized as follows (we will use, for the most part, the symbols adopted by him):

Let us assume a group of firms, for each of which can be solved a problem of choice of the optimum combination of productive activities in terms of linear programming.

For enterprise i the problem may be formulated as follows:

To maximize

$$\pi_i = z_i' x_i$$

subject to

$$B_i x_i \leq c_i$$

The corresponding dual may be formulated thus:

To minimize

$$\rho_i = c_i' r_i$$

subject to

$$B_i' r_i \geq z_i$$

---

[1] More recently, Thomas A. Miller [2] showed that conditions less restrictive than those proposed by Day are sufficient to ensure equality between the solution of the aggregate model and the sum of the solutions of the single models. However, the conditions of Day, unlike those of Miller, also ensure proportionality between the vectors of the aggregate and the individual solutions; this allows considering of the proportions between the levels of different productive activities that are derived from the solution of the aggregate model as optimum proportions between the levels of the same processes for each firm of the group.

The same problem, formulated for the aggregate of the firms of the group will be:

To minimize

$$\pi = z'x$$

subject to

$$Bx \leq c$$

and the dual:

To minimize

$$\rho = c'r$$

subject to

$$B'r \geq z$$

in which

$$c = \sum_i c_i \qquad (1)$$

and

$$z = \sum_i \alpha_i z_i \qquad (2)$$

Let us indicate by x_i^* and r_i^* the vectors of the solutions of the primary and dual problems of the i-th firms and by x^* and r^* the corresponding solutions of the aggregate problem. Sufficient conditions for ensuring that the results of the aggregate problem are not biased, that is, in order to obtain

$$X^* = \sum_i x_i^* \quad \text{and} \quad r^* = \sum_i \alpha_i r_i \qquad (3)$$

are, according to Day [1, p. 802]:

$$B_i = B_j = B \qquad (4)$$

$$c_i = \lambda_i c \qquad (5)$$

$$z_i = \gamma_i z \qquad (6)$$

$$\sum_i \alpha_i \gamma_i = 1 \qquad (7)$$

The last condition, in particular, is required so that the second of the equalities (3) can be verified; it would not be necessary if one wished to consider exclusively the results of the primary problem.

Our observation concerns specifically this last condition. In our view, it is not necessary even in relation to the results of the dual problem, in the sense that it necessarily holds every time condition (6) holds.

This can probably be clarified in several ways. Substantially, the question is to show that not only do the single values γ_i depend on the choice made regarding the α_i (in (2)), as is intuitive, but that the relationship existing between α_i and γ_i is such that if (6) is valid, and if the process of aggregation (2) is followed, (7) necessarily holds.

In fact, if (2) and (6) are both valid, we can write

$$\frac{1}{\gamma_i} z_i = \sum_i \alpha_i z_i \qquad (8)$$

Since the z_i represent vectors and γ_i and α_i are scalars, (8) is an equality between vectors. Taking the k-th elements in each of these vectors, we can therefore write

$$\frac{1}{\gamma_i} z_{ik} = \sum_i \alpha_i z_{ik} \qquad (8a)$$

from which comes

$$\gamma_i = \frac{z_{ik}}{\sum_i \alpha_i z_{ik}} \qquad (9)$$

which is the relationship that links the values of γ_i and α_i. It is clear that since the equality (8a) holds for all the corresponding elements of the vectors that appear in (8), the value of γ_i that can be obtained from (9) remains constant with the variation of the index k and depends only on the index i, which characterizes the element that represents the numerator of the fraction. It thus appears evident that once the value of the α_i is established, the value of the coefficient γ_i relative to each of the vectors z_i is unequivocally determined. Using (9) to calculate the value $\sum_i \alpha_i \gamma_i$, we obtain

$$\sum_i \alpha_i\gamma_i = \sum_i \alpha_i \frac{z_{ik}}{\sum_i \alpha_i z_{ik}}$$
$$= \frac{\sum_i \alpha_i z_{ik}}{\sum_i \alpha_i z_{ik}} \equiv 1$$

With this it is clear that the observations of Day [1, p. 803] concerning the possibility and the method of choosing suitably the α_i are meaningless. In these observations he seems to think that once the α_i are chosen, it should still be possible to choose between different values of γ_i without taking into account that the first choice implies also an unequivocal determination of the coefficients of proportionality.

EXACT AGGREGATION WITH LINEAR PROGRAMMING MODELS— A NOTE ON THE SUFFICIENT CONDITIONS PROPOSED BY R. H. DAY: REPLY

The redundancy in my aggregation theorem is clearly exposed by Marenco, and we can conclude that a proportionally heterogeneous aggregate can be represented by a single linear programming problem based on aggregate resources, as the aggregation theorem states, but with no further conditions. However, my statement about the choice of the aggregation weights (the α's) [1, p. 803] is not entirely meaningless, as Marenco asserts. We should merely make it stronger. For a pecuniously proportional aggregate, *any* weighted average of objective functions will do. Since the objective functions are proportional to each other, they are proportional to their average and the γ_i's needed for the theorem always exist.

This does *not* mean that any conditions of the theorem have been relaxed, only that one condition is implied by the others. Marenco is clear on this point· But a desire to obtain less restrictive hypotheses that would justify larger aggregates is a kind of theoretical snipe, which in between times has led some investigators off on what seems to me to be a pointless hunt.

Miller [6, p. 54], for example, hopes to get around the straight-jacket of proportionality by defining exact aggregation in terms of "qualitatively homogeneous output vectors," vectors whose optimal bases (including slacks) are the same for each firm. Unfortunately, his "theorem" leads to the following procedure: (1) Estimate the z_i, E_i, and c_i matrices for each farm $i=1, \cdots, n$. (2) Formulate and solve each l.p. problem; observe for each problem the optimal basis. (3) Group those farms together that have common optimal bases. (4) Aggregate the resources for these farms and solve the aggregate l.p. problem. In short, to obtain the aggregation solution we must obtain the individual solutions, *precisely the thing we were trying to avoid in the first place.*[1] Besides, the optimal basis depends on both z_i's and the c_i's, so that the groupings are not in general invariant to price mapping. We need the latter computation to get short-run output supply functions and input demand functions, which of course is one of the major applications of aggregate models. Instead of being "less than ideal" [6, p. 56], Miller's result is not an aggregation therem at all. It is merely a property possessed by the solutions of n individual l.p. problems with the same dimensions.

In an effort to overcome the shortcoming in Miller's approach, Lee [4] proposed to aggregate farms with identical dual solution vectors.[2] He thought this pointed the way to a true aggregation interpretation. Unfortunately, what is true of primal solutions is true of the dual solutions: they depend—both the levels and the bases—on *all the coefficients* of the matrices z_i, B_i, and c_i. To find the range of resource ratios over which the dual solution is constant would require parameterizing the l.p. problem for one firm for all possible variations in those ratios. Moreover, if we allow for variations in profit expectations, we must also parameterize the l.p. problem for all possible variation in the profit coefficient ratios. This leads to an inordinate number of computations, perhaps even more than required by directly computing the n individual l.p. solutions and adding them up.

The latter possibility is clarified by reasoning as follows: Let each member of a group of n firms be represented by an l.p. problem of the same dimension (m activities and k rows) with technological homogeneity ($B_i = B_j$, $i, j = 1, \cdots, n$). Let $\alpha = \max\{k,m\}$ and $\beta = \min\{k,m\}$. Then the number of groups into which the firms must be divided for exact aggregation within groups is bounded above by the number

$$(1)\quad \nu = \sum_{i=0}^{\beta} C(\alpha, i)C(\beta, i) = C(k+m, k)$$

where $C(p, q)$ is the number of combinations of p things taken q at a time. This number is equal to the maximum number of square matrices that can be formed from a B_i matrix or, as indicated by the last expression on the right, it is equal to the number of k dimensional square matrices that can be formed from a $k \times (m+k)$ matrix (B_i, I), where I is a $k \times k$ identity matrix representing "slacks" [2, p. 47].[3]

To illustrate: Suppose $m = 20$ and $k = 20$, a relatively small size for representing farm decisions by modern standards. The first term in the expansion (1) is 400 and the second is 36,100. The ninth term is the *square* of 184,756. The minimum number of subaggregates is thus in the hundreds of millions, many more than there are farms in the United States, which now number about 4,000,000.[4]

---

[1] On this point see also [7].

[2] Incidentally, Lee is wrong in thinking, as he asserts on p. 59, that the individual firm dual variables in a proportionately heterogeneous aggregate are weighted by the relative share of the ith firm of the industry's aggregate resources. The weights are arbitrary, as re-emphasized above.

[3] The reason ν gives an upper bound and not the exact number of subaggregates required is because some (usually many) of the square matrices formed will be singular and not eligible as optimal bases. Only for models with special restrictions on the contents of the B_i matrices can an exact number be computed. An example is given below for the "Henderson Model."

[4] In Lee's graphical analysis $m = 3$, $k = 2$, so that $\nu = 10$ subaggregates (at most) required for exact aggregation. Lee, on the basis of graphical reasoning, obtained four

The *least* upper bound on the number of farms depends on the exact structure of the B matrix and may be much lower than given by formula (1). For example, if we assume a pure Henderson model [3; 2, Ch. II] with m crops so that $k = 2m+1$, we find that the exact number of nonsingular square matrices (bases) is

$$\nu' = \sum_{i=0}^{m} C(m, i) + m \sum_{i=0}^{m-1} C(m-1, i) = (m+2)2^{m-1}. \tag{2}$$

This is a much smaller number than the ν of equation (1). Suppose now that we consider an industry, each firm of which produces the same 20 commodities and determines production according to a pure Henderson model. Then $\nu' = 22(2^{21}) = 1{,}048{,}576$—more than 25% of the farms in the U.S.—and this is an oversimplified model indeed! Mighell and Black [5] indicated a sampling rate of 12 to 25 percent in order to obtain a good approximation to exact aggregation. Lee's procedure—even for a highly oversimplified model that gives the most favorable conditions—indicates a number of subaggregates at the upper limit of this amount.

We must, I think, reluctantly conclude that (1) it is likely that the maximum number of aggregates that could be identified by a sufficient amount of parametric programming would exceed the number of farms we have to aggregate in the first place; and (2) even if it does not, it will probably exceed the number (by several orders of magnitude) that we can afford to estimate and compute. While Lee was correct in guessing at a finite bound, he apparently overlooked the combinatorial properties of optimal bases in $m+k$ dimensions. I believe none would argue that the development of a million micromodels is economical, let alone feasible. Indeed, it seems we must look to other means of justifying the representative firm, microeconomic approach for estimating aggregate relationships—if we are to justify it at all.

RICHARD H. DAY
The University of Wisconsin

---

required subaggregates, but that result is based on the assumption that all producers have identical costs and returns expectations. The number derived here includes the possibility that within each resource grouping firms can have different profit expectations and must likewise be grouped according to profit ratio variations within which the optimal bases will not change.

MYSTERIOUS MULTIPLIERS: COMMENT

In their recent article, Mirakhor and Orazem reach an interesting conclusion, namely, that in Kansas "a dollar of farm income generates more than twice as much total income as a dollar of nonfarm income" [1, p. 920]. They arrive at this conclusion first by developing farm and nonfarm income "multipliers" and then by comparing them. While their results are tantalizing, their "multipliers" are mystifying.

Mirakhor and Orazem define α_t to be the proportion of total income coming from the farm sector and β_t to be the proportion of total income from the nonfarm sector. Expressed in equation form [1, p. 915, equations (2) and (3)]:

$$\alpha_t = \frac{YF_t}{Y_t} = \frac{\text{Farm income in period } t}{\text{Total income in period } t}$$

$$\beta_t = \frac{YNF_t}{Y_t} = \frac{\text{Nonfarm income in period } t}{\text{Total income in period } t}$$

The authors then deduce the farm income "multiplier" to be $1/(1-\beta_t)$ and the nonfarm income "multiplier" to be $1/(1-\alpha_t)$ [1, p. 916].

Since total income is the sum of farm and nonfarm income [1, p. 915, equation (1)], substitution for alpha and beta will give:

$$\frac{1}{1-\beta_t} = \frac{Y_t}{YF_t}$$

$$\frac{1}{1-\alpha_t} = \frac{Y_t}{YNF_t}$$

What disturbs us most about the analysis is why anyone would think that total income divided by farm income or total income divided by nonfarm income in any way reflects income-generating effects. On the basis of this type of reasoning, the "multiplier" for the buggy-whip industry would be astronomical!

Perhaps there is a lesson to be learned here about deriving multipliers. When Lord Keynes derived his famous investment multiplier, he used a behavioral equation (the consumption function) and the accounting identity that total income equals consumption plus investment. Apparently Lord Keynes was not a clever enough mathematician to derive his multiplier only from the accounting identity.

MYSTERIOUS MULTIPLIERS: REPLY

Farrish and Hardie seem to be suffering from "tunnel-vision syndrome." Their entire objection to our article can be summarized: "It can't be done this way; otherwise, Lord Keynes would have done it." Their objection is based on this weak form of "appeal-to-authority" line of logic. Overwhelmed by their enthusiastic skepticism, they have missed an essential aspect of the analysis.

Let us develop an argument similar to that of Farrish and Hardie. We start with an accounting identity [1, p. 115]:

$$Y = C + I \tag{1}$$

where Y is income; C, consumption; and I, investment. Now let (1) change by Δ to give us

$$\Delta Y = \Delta C + \Delta I \tag{2}$$

divide (2) by ΔY

$$1 = \frac{\Delta C}{\Delta Y} + \frac{\Delta I}{\Delta Y} \tag{3}$$

Let us designate $\Delta C/\Delta Y = \alpha$; (3) now becomes

$$1 - \alpha = \frac{\Delta I}{\Delta Y} \tag{4}$$

or

$$\Delta Y = \frac{1}{(1-\alpha)} \Delta I$$

or

$$\frac{1}{1-\alpha} = \frac{\Delta Y}{\Delta I}$$

where $1/1-\alpha$ is the Keynesian multiplier derived from the accounting identity.

We can now ask the following question: Why should anyone think that a change in income divided by a change in investment in any way reflects income-generating effect. Obviously, there is more to the analysis than the simple mathematical derivation. Confronted with such a question, which may have well been asked in an introductory economics course, one would have to explain the importance of the exogenous determination of investment and the linkage process existing between investment and income.

That is precisely what we tried to do in the early stage of the analysis and summarized the argument in Figure 1 of the article [2, pp. 913–914]. We set up a linkage process that relies on the "export-base" theory of the regional economists. To restate our case, we are talking about an agriculturally oriented economy with these characteristics: (1) farm income is a substantial portion of the total income in the economy; (2) there are major industries in the economy that have either forward or backward linkages with the farm sector; (3) a major portion of the demand for the output of the farm sector is exogenously determined; and (4) the farm sector contributes a major portion of its income to the nonfarm sector via (a) farm production expense and (b) farm sector's direct consumption of nonfarm sectors' output.

The "buggy-whip" industry of Farrish and Hardie, having none of those characteristics, is totally irrelevant in the linkage process, which Farrish and Hardie apparently missed.

A NOTE ON THE MEASUREMENT OF PRICE ELASTICITY OF DEMAND

The November 1968 article by Lyon and Simon [1] presents an interesting and useful measure of price elasticity of cigarettes. I would not hesitate to use their approach given similar circumstances—at least as a check on other methods, and possibly as the preferable method.

However, the approach has a few problems of its own, so that the case for selecting it over other methods is somewhat overstated in the November article. Some of these problems are correctable—at least approximately—so it may be useful to discuss them. In some special cases no corrections will be needed, but it is advisable to try to determine such cases through analysis, rather than assume it at the outset.

The most obvious and important problem is that the approach recommended skirts the issue of the demand function underlying the elasticity estimate. Subtracting $(Q_3-Q_4)/Q_4$ in the "control" cities implies the authors had in mind an additive model, but nowhere do they indicate they have considered this question. A model linear in logs might seem more reasonable for cigarette demand; if so, this would suggest dividing by $(Q_4-Q_3)/Q_3$—not subtracting. The latter could produce significantly biased estimates of elasticity. In any case, it is clear that the adjustment represented by $\Delta q/q$ is best derived from a consciously chosen model and is *not* the same for all models.

A second problem, related to the first, is the assumption (again not explicitly stated) that the factors implicitly represented by $(Q_4-Q_3)/Q_3$—i.e. all non-price factors, such as economic or population growth—remain the same in the "test" city as in the average of the "control" cities, over the time period used. This is not only highly questionable, but is very unlikely to be the best (or even a very good) way of adjusting for such non-price variables. Cigarette demand is very likely to be dependent on population and economic growth, for example. Such growth is measurable and different among states. Even a rough recognition of this in the method—surely possible—would be better than assuming that no differences existed.

A simplified example might help illustrate the above points: Suppose demand for cigarettes were a function, linear in the logs, of price and disposable personal income:

$$q = a_0 P^{a_1} E^{a_2}$$

with values

$$a_0 = a_2 = 1$$

and

$$a_1 = -1$$

or

$$q = P^{-1}E$$

Then, by definition, $\epsilon = (dq/q)/(dp/p)$; or $\epsilon = -1$.

And suppose values of the variables (measured relative to quantities at Time 1) are:

Time	"Test" city			"Control" cities (average)		
	q	p	E	q	P	E
1	1	1	1	1	1	1
2	1.32	.833	1.10	1.10	1	1.10

Then arc elasticity, as measured by the authors, is:

$$\epsilon_{\text{arc}} = \frac{(\Delta q/q)_T - (\Delta q/q)_c}{(\Delta P/P)_T}$$

$$= \frac{.32 - .10}{-.167} = -1.32$$

Thus, when this model applies, which is not unreasonable for cigarette demand (except that more variables might be needed), the proposed method results in a 32 percent bias. The bias would be reduced to 20 percent if we *divide* $(\Delta q/q)_T$ by $(\Delta q/q)_c$. In this example, the remaining bias is due to using $\Delta q/q$ for dq/q for moderately large price changes. This error is not incurred when elasticity is derived directly from the model.

If, as implied by the method, a linear model is adequate for explaining cigarette demand, then it is even more important to explicitly recognize the assumed model, since price elasticity will not be constant for different levels of price and quantity.

An additional bias would have occurred had we not assumed equal change of +10 percent in the economic variable.

The above discussion is not intended to discredit the authors' approach. I consider it very helpful in many circumstances and have frequently used it. Rather, I am suggesting that the approach would benefit from a more careful and explicit consideration of the underlying demand model, and from a more careful and explicit consideration of the non-price variables involved. There are several ways this could be done, including combining time series analysis with the authors' approach in a multi-stage procedure. The results would be both theoretically and practically more satisfying and convincing than those presented in the November article.

ECONOMICS OF COST-SHARE LEASES: COMMENT

In an article entitled "Economics of Cost-Share Leases in Less-Developed Countries," Adams and Rask [1] offered a cumbersome geometrical analysis, which led them to show the following:

(a) A *traditional lease* leads to a use of variable factors of production that is short of the use under the assumption of perfect competition and no lease.

(b) An *ideal lease* leads to a normal use of variable factors of production. That is, an ideal lease leads to profit maximization identical with what would have been under perfect competition and no lease.

(c) Replacing the *traditional lease* by an *ideal lease* leads to a *cost-sharing puzzle*: The tenant would definitely benefit from adopting the *ideal lease* instead of the *traditional lease*; the landowner may or may not.

(d) *Traditional leasing* arrangements are exploitative: The tenant receives a smaller net return under *traditional leasing* arrangements than he could have received under an *ideal leasing* arrangement.

Since traditional leasing arrangements are exploitative, Adams and Rask conclude erroneously that some type of societal pressure should be applied in order to force landowners to participate in paying variable costs.

For the benefit of the reader, it is recalled that the *traditional lease* is an arrangement in which the landowner does not participate in paying variable costs. In return for using the land, the tenant pays the landowner a certain proportion of the crops. The *ideal lease* is an arrangement in which the landowner participates in paying variable costs in the same proportion as he shares crops.

The Correct Analysis

Let us start the analysis by focusing on an individual farm that utilizes three factors of production, A_1, A_2, and A_3. A_1 and A_2 are variable factors; A_3 is fixed. The farm sells its output at a price of P, and pays prices P_1 and P_2 for the variable factors. Let the production function be

$$Q = f(A_1, A_2, A_3) \tag{1}$$

Then under the traditional leasing arrangement where the landowner shares half of the crops, the tenant would attempt to maximize the following profit function

$$\pi = 1/2PQ - P_1A_1 - P_2A_2 - P_3A_3 \tag{2}$$

Differentiating (2) with respect to the variable factors of production and setting the derivatives equal to zero gives

$$\begin{aligned} \frac{\partial \pi}{\partial A_1} &= 1/2p \cdot f_1 - p_1 = 0 \\ \frac{\partial \pi}{\partial A_2} &= 1/2p \cdot f_2 - p_2 = 0 \end{aligned} \tag{3}$$

where

$$f_1 = \frac{\partial Q}{\partial A_1} \quad \text{and} \quad f_2 = \frac{\partial Q}{\partial A_2}$$

$P \cdot f_1$ is the marginal value product (MVP) of A_1 and $P \cdot f_2$ is the marginal value product of A_2. Accordingly, (3) can be written as

$$\begin{aligned} 1/2(MVP)_1 &= p_1 \\ 1/2(MVP)_2 &= p_2 \end{aligned} \tag{4}$$

Relations (4) prove proposition (a), namely, that a traditional lease would lead to under-utilization of variable inputs. Instead of seeking a level of output at which the prices of the inputs are equated with their respective marginal value products, the tenant would seek a lower level of output at which the prices of the variable inputs are equated with half of the respective marginal value products.

Suppose the traditional lease is replaced by an ideal lease. The landowner participates in paying half the total variable cost. The profit function considered by the tenant is

$$\begin{aligned} \pi^* = 1/2PQ - 1/2(P_1A_1 + P_2A_2) \\ - P_3A_3 \end{aligned} \tag{5}$$

Differentiating (5) with respect to the variable factors of production A_1 and A_2, and setting the derivatives equal to zero gives

$$\begin{aligned} \frac{\partial \pi^*}{\partial A_1} &= 1/2p \cdot f_1 - 1/2p_1 = 0 \\ \frac{\partial \pi^*}{\partial A_2} &= 1/2p \cdot f_2 - 1/2p_2 = 0 \end{aligned} \tag{6}$$

This proves proposition (b), namely, an ideal lease leads to a normal use of variable factors as follows:

$$\begin{aligned} (MVP)_1 &= P_1 \\ (MVP)_2 &= P_2 \end{aligned} \tag{7}$$

One does not need to "toy" with much geometry to prove proposition (c). Under both arrangements we can look upon the tenant as a producer who, out of each additional pair of units of output, retains one unit for himself and gives one to the landowner. This means that for the tenant, the extra cost of producing one additional *retained* unit under a traditional leasing arrangement is twice the extra cost under the ideal leasing arrangement. Thus, if the price of output does not change, the tenant would always benefit from switching to the ideal leasing arrangement. To show that the landowner may or may not benefit from the switch, consider the following Cobb-Douglas production function:

$$Q = KA_1^{\alpha}\cdot A_2^{\beta}\cdot A_3^{\gamma},\quad \alpha+\beta+\gamma = 1 \tag{8}$$

Let A_1 and A_2 be the variable inputs and let A_3 be land. Let Q_0 be output under traditional leasing arrangements and Q_1 output under an ideal leasing arrangement. Then, under the traditional lease the rent of the landowner is $1/2Q_0P$, and under an ideal lease his rent amounts to $1/2Q_1P-1/2(\alpha+\beta)Q_1P$ which is equal to $1/2\gamma Q_1P$. The expression $1/2\gamma Q_1P$ may be either lower or higher than the expression $1/2Q_0P$. This is true because $Q_1>Q_0$ and $0<\gamma<1$.

Who Exploits Whom?

Dale and Rask imply that the tenant is exploited under the traditional leasing arrangement. They prove it by resorting to geometrical analysis to show that an ideal lease would yield a higher income for the tenant than the traditional lease.

But suppose for the sake of argument that one wants to adopt the criterion of paying resources according to their value of marginal physical product. Then clearly the one who is being exploited under the ideal lease is the landowner who receives only half of the VMP of land which, under the assumption of a Cobb-Douglas production function, is γQ_1P. If in our example the tenant provides input A_1, then under the ideal lease the tenant exploits the landowner: In addition to αQ_1P which is his VMP, he is paid $1/2\gamma Q_1P$, which is a half of the VMP of land. This leaves the landowner with only a half of what he "deserves."

A Fallacy of Composition

Suppose, again for the sake of argument, that tenants are exploited. Would some type of societal pressure on landowners to accept ideal leasing arrangements be beneficial to tenants? The answer to this question is not necessarily positive. It can be shown that, given a certain aggregate production function and some realistic assumptions concerning price elasticity of the demand function for farm output, tenants might lose from switching to the ideal lease. To illustrate such a possibility, consider a farm sector whose production process can be approximated by some Cobb-Douglas function. Assume further that farmers as a whole are confronted with an aggregate demand function for output with price elasticity of $-1/2$.

Suppose that, under the traditional lease, the system can be described as follows:

(9)

Demand:

$$Q = 20P^{-1/2}$$

Production Function:

$$Q = A_1^{1/4}A_2^{1/4}10^{1/2}$$

Factor A_1:

$$1/2\left(1/4\frac{Q}{A_1}\right)P = 1/2,\quad P_1 = \$1/2$$

Factor A_2:

$$1/2\left(1/4\frac{Q}{A_2}\right)P = 1/2,\quad P_2 = \$1/2$$

System (9) is in equilibrium when $A_1=A_2=10$, $P=\$4$ and $Q=10$. The net profit of tenants is calculated as follows:

$$\begin{aligned}\text{Net profit} &= 1/2Q_0\cdot P_0 - A_1^0P_1 - A_2^0P_2\\ &= 1/2\ 10\cdot 4 - 10\cdot 0.5 - 10\cdot 0.5\\ &= \$10\end{aligned}$$

where A_1^0 and A_2^0 denote A_1 and A_2 under the traditional lease.

Switching from the traditional lease to the ideal lease, the system becomes

Demand:

$$Q = 20P^{-1/2}$$

$$
\text{(10)}\quad
\begin{aligned}
&\text{Production Function:}\\
&\qquad Q = A_1^{1/4}A_2^{1/4}10^{1/2}\\
&\text{Factor } A_1:\\
&\left(1/4\frac{Q}{A_1}\right)P = 1/2, \qquad P_1 = \$1/2\\
&\text{Factor } A_2:\\
&\left(1/4\frac{Q}{A_2}\right)P = 1/2, \qquad P_2 = \$1/2
\end{aligned}
$$

System (10) is in equilibrium when $A_1 = A_2 = 15.87$, $p = \$2.52$ and $Q = 12.6$. The net profit of tenants is calculated as follows:

$$
\begin{aligned}
\text{Net profit} &= 1/2Q_1P_1 - \tfrac{1}{2}[A_1{}^1P_1 + A_2{}^1P_2]\\
&= \tfrac{1}{2}\,12.6 \times 2.52\\
&\quad - 1/2[15.87\cdot 0.5 + 15.87\cdot 0.5]\\
&= \$7.95
\end{aligned}
$$

where $A_1{}^1$ and $A_2{}^1$ denote A_1 and A_2 under the ideal lease.

That is, if one is careful to avoid falling into the trap of the *fallacy of composition*, or, if one does not forget that when national policies are involved prices of outputs can no longer be assumed constant, then one can show that tenants will not necessarily benefit from switching to the ideal lease. I don't believe that Adams and Rask could claim that my assumptions, as presented in equations (9) and (10), are unrealistic. There probably are underdeveloped countries in which the price elasticity of demand for output is higher than the absolute value of $-1/2$, as well as countries in which it is lower than the absolute value of $-1/2$. But, on the whole, once the demand curve for farm output becomes inelastic, one cannot unambiguously claim that the traditional lease is exploitative. As shown in our model, under the traditional leasing arrangement tenants received \$10, while under the ideal lease their net gain was reduced to \$7.95.

It is impossible to determine unambiguously who exploits whom. Even if we consider a single farm for whom the price of output is constant, it is possible to show that landowners are exploited under the ideal lease, provided that our welfare guiding rule is paying inputs their value marginal products.

A national policy aimed at switching from a traditional leasing to ideal leasing arrangement might impoverish tenants. This is in particular likely if the aggregate demand for farm output is inelastic with respect to price.

ECONOMICS OF COST-SHARE LEASES: A REPLY

We are pleased that Professor Gisser was sufficiently interested in our article, and particularly in one of the footnotes, to work up an alternative presentation of our argument. This he does in the first part of his comment. He is apparently disturbed by the geometry rather than by our conclusions, since he agrees that tenants will always benefit by adopting a cost-share lease and that landowners may not. He is thus in full accord with our main point that market forces in LDC's will probably not be sufficient to resolve, through cost-sharing, the resource inefficiencies involved in share-rental arrangements. Aside from the capacity to generalize for more than one variable input, his analysis is identical with our own.

Gisser goes on to question our normative definition of exploitation: A tenant is exploited to the extent he realizes less under a non-cost-share lease than under cost sharing. As an alternative, he suggests that exploitation be defined on the basis that an owner of a resource *ought* to be paid the value of its marginal product. Although sanctified by economic usage, his definition is also normative. This is not surprising since exploitation is an emotive, value-laden term which cannot be defined objectively.

Although we are not married to our particular definition of exploitation, we do feel that it is operational and can be useful in addressing major policy issues. For example, from a social viewpoint important inefficiencies in resource utilization result from share leases in LDC's. Commonly, widespread poverty also exists among tenants, and short falls occur in agricultural output. All three of these problems can be at least partially alleviated by eliminating exploitation as we define it. As we suggest in our paper, cost-share leases are only one of the tools that might be used. A strong argument for land reform could also be made.

Somewhat different policy conclusions might be drawn from Gisser's definition: (1) Landlords are likely to be "exploited" through adoption of cost-share leases. Policy conclusion: traditional leases are more desirable. (2) It is very likely that many landlords are also being "exploited" under traditional leases. Following Gisser's formulation, and assuming a traditional lease, it is very possible that the payment made to tenant's labor, if based on its VMP, would be less than his share of total output. Policy conclusion: remove the tenant from the land or lower the share of output that he receives. (3) If a tenant's VMP for his labor is low, it implies that he is providing a poor quality input and should be rewarded on that basis. Policy conclusion: most of the income stream should go to the landowner; land has no particular social function and Ricardian rent does not exist; Malthus should reign; the distribution of landownership is inviolable; tenants should be denied access to activities that are almost synonymous with control of land, such as education, political power, and health services; tenants in countries like Bolivia were not justified in forcing land reform since they may have already been taking advantage of landowners under their traditional leases.

In the last part of his comment, Gisser is of course correct in stating that increased output resulting from resolution of resource inefficiencies inherent in share leases could have an adverse price-income impact on tenants. His assumptions, however, are rather restrictive. We readily grant that farmers in LDC's face a domestic aggregate demand schedule that is inelastic. The following qualifications, nevertheless, might alter his conclusions: (1) share tenants may only produce and market a small part of total output; (2) tenants may be producing commodities that have relatively high price elasticities; (3) increased output may substitute for imports and have little or no impact on domestic prices; (4) technological innovations may substantially reduce production costs so that tenants realize more net income in spite of lower product prices; (5) substantial amounts of increased production might be consumed on-farm and have little-or-no effect on product prices; and (6) major increases in agricultural output may be absorbed by demand schedule shifts which result in little price change. This will likely occur because of the rapid growth in population, expanding incomes coupled to high average and marginal income elasticities of demand for agricultural commodities, and rapid growth in demand for agricultural raw materials to fill industrial needs.

Professor Gisser's quest for the black-hat-wearer in the tenant-landowner relationship will not be very useful to the social minded, equity oriented policy maker, but should warm the cockles of landlord's hearts.

TRAINING FOREIGN GRADUATE STUDENTS IN AGRICULTURAL ECONOMICS: FURTHER COMMENT

This is a rejoinder to the thoughtful and constructive comment of Professor Heraclio Lombardo [1] on my article on the training of foreign graduate students [2]. I wish to endorse or supplement some of his suggestions and observations and to carry further certain statements that I made in the article.

Professor Lombardo notes that Latin America is part of the Western World and is therefore, presumably, heir to the "Greek" system of thinking; yet, many Latin American students suffer disabilities such as he has noted in their efforts to develop scientific procedure in working on agricultural problems and policies, just as if they did not have a "Greek mind."

The practical problem certainly is as Professor Lombardo has described it and, in my observation, the basic reason is that yes, indeed, the typical Latin American scholar does not have a Greek mind, even though his ancestors once did. The accomplishments and attitudes of the Greek mind, which forever sought for the causes of all things observed by the senses, were passed on to the Western World, including Italy and Spain, in the Renaissance. As far as science was concerned, the important thing that was reborn was the *search* for an improved understanding of this world's phenomena, for which freedom of thought and expression was essential. In those parts of Europe where the Protestant Reformation of the 16th Century was successful enough to break the governance of the Church over the procedures and conclusions of inquiries into the natural order, the scientific Renaissance survived and continues down to our own day; but in such countries as Spain and Italy, inquiry was stifled through an authoritarian control of thought as soon as the Church discovered that the results were not in accord with received doctrine, and the newly reforged connection with the Ancients was thus again broken.

Another very important difference which arose was that in countries where Protestantism could not be suppressed, and religion for a majority or a substantial minority came to rest on the individual's interpretation of the written Word, more than on the dictates of Church authority, a zeal for promoting literacy among the general, humble populace was suddenly born; but no such zeal, except perhaps in some cases in recent years, was ever felt in countries where the Reformation utterly failed or did not occur, or in the former colonies of such countries.

The world over, the nature and quality of thought on religion and on other most basic philosophical matters sets the tone of *all* thought. It also conditions the purpose, and therefore the method, of education. Science can hardly be really indigenous where freedom of inquiry and expression in these more fundamental fields does not also fully prevail.

A practical illustration of how the tradition of authoritarianism in thought affects the progress of science may be useful. In visiting a remote branch experiment station in one of several Latin American countries where I have worked, I observed that the young scientists there, of whom some had been trained in the U.S.A., had been supplied with U.S. autoclaves and other expensive research machinery of recent design but lacked the electric power and hot water connections that were necessary in order to operate these machines. They also had no scientific library. To my suggestion that they write to their superiors in the capital city and explain their situation and how little it would cost to correct it, they replied, "You don't understand. In this country we are organized on the basis of the *principle of authority.* All suggestions must therefore come from the top down, and if we wrote such a letter as you suggest we should probably lose our jobs."

Other illustrations could be given. I would not wish to leave the subject without saying, however, that there are signs of lessened authoritarianism and a growth of freedom of thought within the Church in Latin America, and that these may be among the most hopeful signs now visible that science and its benefits may eventually become truly indigenous there.

Passing on to other points made by Professor Lombardo, I agree that the training of foreign students should certainly include the "theoretical, philosophical and empirical conception and application" of research. In discussing the principal subjects that I thought they should study, I had in mind, without saying so clearly enough, that research methods, research results, and the use of research results should be taught as an integral part of each subject mentioned. I believe that instruction on research has to be made very specific and must include actual research itself, if it is to be truly effective, and so am inclined to favor a succession of research experiences and a succession of illustrations of how the results of research have influenced the formation of principles, in the teaching of each subject. I think that this would weave the necessary connection of principle to reality that is lacking in the non-Greek mind, as well as supply the needed tools of inquiry. If a *generalized* course in research methods were given, I would suggest that this be done after students had become thoroughly familiar with the aspects of research that Professor Lombardo has so well stated, but through observation, instruction, and experience of research on very concrete matters. A general course might then serve to consolidate and systematize the student's previous learning in this field.

My feeling about a course in logic is somewhat similar. If it were given early and as a hoped-for means of promoting logical thought on concrete subjects to be studied later, I anticipate it would merely be memorized, just as mathematics generally now is, as an easy course in which to make a good grade, and that it probably would not affect the quality of subsequent thinking on any aspect of reality. At the very end of training, however, after the student had learned to think logically on concrete propositions by being assisted to do so, in case after case, then I think perhaps a course in logic would be useful in codifying and systematizing a way of thinking in which the student had already become proficient in a practical way. Thus, in respect to courses in *general* research method and logic, I feel that the psychologically efficient order of procedure is probably not what might seem logical at first.

A good course in agricultural policy, I agree, would offer an excellent chance for the student to bring to bear on large questions currently being debated in his country and in our own the information and the scientific system of thought which he would have acquired in wrestling with the more basic subjects such as farm management, marketing, prices, and the like.

As to prices, in these days when—I believe because of national and international monetary policies—the international terms of trade of nations selling mostly farm products and other basic goods have become so unfavorable, it seems to me that instruction in price-making factors and how they actually operate would be one of the foundations for a full discussion of national agricultural policy. On the difficulties of providing this instruction or of putting it into practice in many of the countries whose students need it, I fully agree with Professor Lombardo, but think that the game will be well worth the candle wherever we can at all manage to play it.

SOME RESPONSES OF RICE FARMERS TO THE PACKAGE PROGRAM IN TANJORE DISTRICT, INDIA: COMMENT

In a recent Ford Foundation study [1] reporting on the responses of rice farmers to the Package Program in the Tanjore District of South India, Malone presented data that show a paradoxical situation—a situation in which hired labor is being used even when "surplus" family labor is available. "Very small" farms use about 24 percent of available family labor; "small" farms, about 22 percent; "medium" farms, 18 percent; and "large" farms, 40 percent. It will be instructive to note that family labor accounts for about 60 percent of all labor used on very small farms; 35 percent on small; 25 percent on medium; and 18 percent on large farms. The rest is hired labor. The question naturally arises: why do Tanjore farmers use hired labor when family labor is available? Malone explains [1, p. 260]:

> . . . Usually less than half of the family's available time was productively employed even on very small farms. Rice growing is messy work under irrigated conditions in India and the farmer excuses himself from working knee-deep in mud in the tropical heat. With wages at 30 to 60 cents per day for men and half that for women, hired labor seems a good alternative even on quite small farms.

Is this a rational economic explanation of the behavior of Tanjore farmers? From the economic standpoint, use of hired labor is inconsistent with a situation where "surplus" family labor is available, unless the farm family attaches a great value to leisure, greater than the wages, as Malone seems to imply. Let us examine the evidence to see whether these farmers are as economically irrational as Malone contends.

The very small farms, averaging 1.4 acres in size, would increase its net income from $115.40 to $146.60 if no hired labor was used. This is an increase of $31.20, by no means a small amount under Indian conditions. These figures apply to 1962–63, when this study was made and when per capita income was about $71. In the light of this information, it should be apparent that hired labor is not, after all, such a good alternative to farmers as Malone has argued. The increases in net farm income for the small, medium, and large farmers average $86.4, $168.7, and $525.2 respectively, if they did not use hired labor. In other words, very small farms would increase their net incomes by about 27 percent; small, medium, and large farms by 34 percent, 33 percent, and 42 percent, respectively, in case no hired labor was employed. Except in the case of large farms, this would seem possible because available family labor is much more than the total amount of labor used. Does not all this suggest that farmers in Tanjore would not employ hired labor if they could possibly avoid it? If that is so, what is the basis of Malone's contention that the rice farmers of Tanjore district prefer leisure to work at such "low" wages?

A closer look at Malone's data would show where he could possibly have made a mistake. According to him, "family labor available is the number of adult males multiplied by 12, plus months of field work actually done by women and children converted to man-months" [1, p. 259]. This is apparently a measure of the amount of labor available for the whole agricultural season. Such a calculation ignores the important fact that the unemployed labor of one period (slack season) cannot be transferred to another period (busy season). At the time of seasonal peak demands there is a shortage of labor, and that explains the use of hired labor.

In trying to measure the "progressiveness" of Tanjore farmers, one criterion Malone used was the rate of use of "package" inputs. He observes [1, p. 262]:

> A rather surprising result emerged. These heavier users of improved practices proved to be, without exception, small or very small farmers who concentrated on

one crop of long duration rice per year. They did get good yields, 3050 pounds per acre as a normal yield, which is about 30 percent above average. But with only one crop to harvest, their total yield per acre of farmland was very little different from that of the average small farmer who double cropped over one-fourth of his acres; however, they did save on hired labor.

The behavior of this group is not difficult to rationalize. Hired labor accounts for the largest single item of expenditure in all categories of farms in Tanjore. Therefore, saving on hired labor whenever possible is a rational economic proposition for the farmer. It would not have been so if it were true that "with wages at 30 to 60 cents per day for men and half that for women, hired labor seems a good alternative even on quite small farms."

OUR JOURNAL—A VIEWPOINT

The editor's note preceding the communications section of *AJAE* points out the appropriateness of suggestions for improving AAEA [1]. This would appear to qualify *AJAE* itself as a legitimate focus for comment.

Beginning with Volume 48, No. 1 (February 1966), the *JFE*, now *AJAE*, became a more frustrating journal because of the adoption of the new reference procedure by which numbers in brackets were put in the text and the reference listing placed at the end of the article. That this procedure is generally in use now and that it simplifies the author's task a little is true. Yet, something is lost.

The purpose of a reference citation, and an extremely useful one, is to relate ideas to the literature from which they come. With the present format of *AJAE*, this is more difficult and ultimately less successful, even with the increased effort by the reader who constantly has to turn to the last page to decipher the bracketed number code. A return to our older form would make *AJAE* more useful to its readers. I share Professor Paarlberg's [4] footnote frustration. I keep wanting to see things at the bottom of the page.

While I am demonstrating what some will see (but I deny to be) as innate intransigence, I may as well mention a more recent change in *AJAE*.

When a man's association with an institution is more important than his name, then we really must be in an "associationistic age" [3]. The *News Notes* [2] feature institutions first and people second. It conserves space, but it makes the section more difficult to digest if the main interest is in friends and not institutions. Although such was certainly not intended, it strikes me as a bit dehumanizing in that it suggests where I work is more important than who I am. Sometimes change is not progress, and I think this is one of those times.

But for the fact that I hypothesize I am not alone in these feelings, this would have been a letter to the *AJAE* editor. Because the hypothesis seems worthy of test, the matter should be on the agenda of all our members; thus, this is not a letter but a communication.

A FEW COMMENTS FROM THE EDITORS— IN RESPONSE AND OTHERWISE

In addition to matters raised by Robert Bevins, some related points needing explanation may justify our adding a fraction to AAEA's financial obligation for the Journal. We have not, however, earned ourselves much space from success in exhortation of authors toward brevity and economy.

Earl Swanson explains that the change in handling references was in part the result of a mutual understanding among editors of social science journals. A standard format was seen by the group of editors as having the advantage "that manuscripts rejected by one journal can be sent immediately to another journal without expensive retyping and increased chances for errors." Earl added: "We also wanted to have a uniform procedure within the Journal"; but he did not explain why our current procedure was the one selected for uniformity.

An earlier change also has been questioned: why did we take the beginning of the table of contents off the front cover? We asked Jim Nielson, in whose editorial regime that occurred. In reply, he first mentioned "esthetics—we could see no reason why a professional journal could not be made more interesting, on the outside at least." (With never-ending display of that exciting plow and eagle, Jim?) Then, after also mentioning orderliness, he got down to the compelling reason: "We discovered that a number of libraries and other institutions cut off and destroy the covers when they bind professional journals." *AER* nullifies this fiendishness by reprinting the beginning part of its table of contents on the first inside page. But that costs something—approximately the equivalent of one of our typical articles every three years—though a lot less than we are now saving on *News Notes, Personal.*

Which is the lead-in to Bevins' second point—that we put "institutions first and people second," in the *News Notes* of the February issue. In February we published 217 personal items (other than obituaries) on 7½ pages. The past system of individualized news notes has required a page for approximately 12½ items. Thus, by not reprinting institutions' names and obvious recurrent phrases, we saved 10 pages. (There are two 10-page articles in the February issue.) But no less important is our belief that readers are interested in the doings of institutions as well as friends. If we had alphabetized, would the personnel dynamics of ERS have been so readily apparent? Or the restaffing of economics at Colorado State?

Further, with respect to institutionalization (our choice over "associationism"), we see no good reason for not presenting the list of doctoral degrees awarded by conferring institutions; our Editorial Council, to the extent of its response to our inquiry, is favorable.

Beyond all other pros and cons, this way of handling news notes and doctoral degrees has the advantage for the editors of automatic revelation and self-chastisement of those failing to report on time (or at any time).

A third question has been raised—regarding the Journal's long-established review procedure. Would-be authors occasionally allege that bias, prejudice, caprice, stupidity, or what not obstructs publication and that reviewers can get away with this because they are anonymous. But reviewers are not anonymous to the editors, nor are their recommendations binding upon us. If we believe we have encountered malevolence (which is almost never) or ineptitude (once in a while) or carelessness (a little oftener but still not frequently), we try to employ an appropriate discount factor. We occasionally obtain reviews that are more deserving of publication than the manuscript reviewed. However, there are proposals (as well as practices in other journals) that the author be anonymous to reviewers. And we have a proposal that would invert our present procedure—author anonymous to reviewers, the latter identified to the author.

With this issue of the Journal, we initiate a *Research Notes* section, or, for older members, we revive the non-communication part of our erstwhile *Notes* section. *Communications* will remain, as of course will *Articles.* With three categories, we believe we will have the flexibility needed to better serve authors and readers.

We hope that those who have discovered new data or have tried or developed new techniques or have something to say on similar matters (including technical approaches used by industry and extension economists) will think of *Research Notes.*

It should not always be necessary to write fulsomely on theoretical background or report data in great detail. Authors occasionally tell us that when their studies have not yet produced enough to justify an article, senior colleagues have advised their sending in a *Communication.* But a *Communication* usually it is not; so please, senior colleagues, hereafter suggest the possibility of a *Research Note* (and be sure that you both look at the rules on the inside back cover).

Communications, minus those items that will be carried as *Research Notes,* will remain about as heretofore. The only reason for "about" is that we want to encourage a broad interpretation of the prefatory *Editor's Note.* Robert Bevins has correctly interpreted it to include *AJAE.* With little strain upon imagination, "topics of in-

Aranda, Sergio, *La Revolución Agraria en Cuba,* Mexico D. F., Siglo XXI, Editores, S.A., 1968, vii + 240 pp. (28 pesos mexicanos)

On January 1, 1959, the Cuban dictator Batista fled Cuba. Barely six months later the new government issued its first land reform law. Four years later this was followed by a second law which abolished all private farms in excess of 67 hectares.

Sergio Aranda does not answer all the questions that a student might ask about what has occurred in the 10 years during which the structure of the country's agriculture underwent a thorough change. Aranda worked eight years in Cuba and has, to all appearances, a detailed knowledge of the land reform, its problems and accomplishments. He is a great admirer of Cuba's achievements and tries to induce his readers to share his enthusiasm. At times, his passion seems to run away with him when he leaves some particularly important growth issues unexplained. His statistical material is thin and not always well presented, although it is not certain whether this is entirely his fault or that of the absence of official data. Nonetheless, Aranda's book is valuable: it is one of the best analyses of the most thorough land reform in Latin America.

There are certain aspects of Cuba's new agriculture that no real development economist can afford to ignore. As in Mexico 58 years ago, Cuba's farm land was controlled mostly by a few owners of large estates, of whom many were foreigners. Agricultural resources were pitifully unused and underutilized. The level of technology was low; rural unemployment high. Today the land is divided, as in some other socialist agricultures (e.g., Poland's or Yugoslavia's), in two large sectors: the state sector, which controls about 70 percent of the farm land; and the private sector, which controls the remainder. This contrasts with the industrial sector, which is almost entirely state owned. The private producers account for 80 percent of Cuba's coffee, 85 percent of its tobacco, and an important share of other products.

Perhaps the most remarkable fact: rural unemployment not only seems to have disappeared but actually has been replaced by an acute shortage of manpower. The cause of this development appears to be the ambitious production plans of the Cuban government and the massive movement of manpower to industries and public work programs. These have made it necessary to draw on volunteers from urban centers as well as on women workers. Here then is a Latin American agriculture where everybody finds a paying job! According to Aranda, the level of living of the rural labor force has been raised substantially although, in contrast with other countries, this seems to have been achieved until now at the expense of the welfare of the urban population. All in all, a sharp contrast with the remainder of the continent where the millions of unemployed and underemployed, whose numbers are rapidly growing, appear to present an almost insoluble problem. An interesting side-aspect of this transformation may be the change in mentality of the Cuban population towards farming and farm work, which in many underdeveloped countries is regarded at best as a fourth-rate occupation.

Another change has been the organization of the labor force. In most of Latin America, farm people are not encouraged to organize. According to the I.L.O., in 1964 about 1 percent of the rural population were members of cooperatives. In the rural communities dominated by the owners of large estates, cooperatives are regarded as subversive. In Cuba, according to Aranda, most of the private producers who are on units up to 67 hectares belong to one of three cooperatives. Obviously without organization, farm people cannot be expected to participate in the realization of the ambitious goals of increased production and diversification. But obviously the organization of farm people could be undertaken only after feudal paternalism had been abolished.

Finally of interest is the awesome infra-structural work in which an underdeveloped country has to engage, when starting from as low a level as Cuba, before it can compete with modern agricultural economies. Here Aranda makes a real contribution when he gives insights into the lack of research and research facilities, the need for raising technological levels and the education of farm people, and the efforts of the Cuban government to overcome them.

Notwithstanding its shortcomings, this booklet deserves to be translated into other languages.

Behrman, Jere R., *Supply Response in Underdeveloped Agriculture. A Case Study of Four Major Annual Crops in Thailand, 1937-1963*, Amsterdam, North-Holland Publishing Company, 1968, xx + 466 pp. ($22.50)

Yotopoulos, Pan A., *Allocative Efficiency in Economic Development*, Athens, Center of Planning and Economic Research, Research Monograph Series 18, 1967, 313 pp. Price unknown.

Economic analysis of agricultural development is becoming increasingly empirical. Theory had its heyday when big decisions had to be made on scanty evidence. Gifted improvisers wove ingenious designs from meager observations to supply rationales for development programs. After further observation, questions began to be asked about the validity of some of the postulates of development theory. Were the Emperor's clothes real?

Behrman and Yotopoulos examine the premise that certain classes of farmers, characterized mainly by the absence from their production techniques of certain supposedly relevant forms of capital, are inherently unresponsive to economic incentives. The reports of these examinations are as interesting for the handling of data problems as for the findings.

The to-do about the profit maximizing question may have reached its peak. But a great deal remains to be done in quantifying supply responses. On this front, economists face a continuing struggle with data problems. The rising level of econometric sophistication imposes frightful data demands, qualitatively and quantitatively. The would-be student of economic processes in societies which have heretofore devoted few resources to the care and feeding of econometricians may be confronted by a nearly complete lack of data, or by masses of data of dubious quality. One can always collect fresh data, as Yotopoulos did, interviewing farmers in the Greek province of Epirus. Or, if the data are abundant, as in Thailand, one might hypothesize that suitable analytical procedures might still extract considerable significant information despite the presence of lots of noise.

Yotopoulos fitted Cobb-Douglas functions to input-output data for one year's activity on 435 farms. He concludes that, ". . . an admirable harmony between marginal productivities and opportunity costs graces the peasant agriculture." His discussion emphasizes how extensively Cobb-Douglas production function analysis depends on assumptions—I counted 96 statements of postulates and assumptions. Many of these need further testing to determine how critical they are for valid conclusions. For instance, what degree of heterogeneity can be tolerated in the output and input variables? Yotopoulos has contributed some innovations in measurement of capital inputs, reported in an article in this Journal, May, 1967, p. 476, and a chapter in *Economic Analysis and Economic Policy*, reviewed in this Journal, February, 1969, p. 225.

Behrman's book is a substantially revised version of his Ph.D. thesis, which received the American Farm Economic Association Award of Merit for outstanding doctoral dissertations of 1966. It presents nonlinear estimates of a Nerlovian dynamic total supply model for each of the four major Thai annual crops (rice, corn, cassava and kenaf) at the *changwad* (district) level of aggregation. The work is tediously thorough with respect to methodology, presentation of institutional and physical backgrounds, and interpretation of results. The thoroughness extends to a bibliography of more than 300 items, covering theory, methodology, and sources of the facts about Thailand. Behrman's principal result: ". . . . in the short run, farmers in underdeveloped countries respond rationally and substantially to economic incentives." This still leaves the question that Behrman poses but disclaims having tried to answer, "What are the problems that retard the long-run transformation of traditional agriculture?"

Kneese, Allen V., and Blair T. Bower, *Managing Water Quality: Economics, Technology, Institutions,* Baltimore, The Johns Hopkins Press for Resources for the Future, 1968, x + 328 pp. ($8.95)

Davis, Robert K., *The Range of Choice in Water Management, A Study of Dissolved Oxygen in the Potomac Estuary,* Baltimore, The Johns Hopkins Press for Resources for the Future, 1968, xvii + 196 pp. ($7.00)

Although containing valuable technical materials, these are primarily books on public policy and institutions for water quality management. Their plea is for a policy and an administrative framework that will examine the full range of existing and prospective technologies to build efficient programs.

Managing Water Quality is a revised and expanded version of *The Economics of Regional Water Quality Management,* written by Kneese and published in 1964. That book had considerable impact among economists and government officials in this field.[1] Like its predecessor, the current volume begins with the physical aspects of water quality and proceeds to apply some of the basic concepts of welfare economics to the problem of waste discharge into rivers, lakes, and estuaries. As in the earlier volume, the analysis is expanded to cover regional water quality management, which combines individual and collective action in managing water quality. This is followed by case studies of a number of public efforts in managing water quality. Finally, the authors discuss the authorities a regional agency requires for effective action, as well as the role of federal, state, and local governments.

New in the present work are summary reports of research on the efficiency of alternative water quality management approaches in the Potomac and Delaware estuaries. The report and evaluation of the activities in the Ruhr area of West Germany is retained. A new chapter gives a necessarily tentative description and evaluation of public approaches to water quality management for three countries in Western Europe and for the Delaware River basin. The discussion of combined individual and collective measures has been supplemented by a rather formidable mathematical appendix, by J. Hayden Boyd. Other portions of the book were in part rewritten, reorganized, considerably expanded, and updated, but are basically similar to the earlier work. The style is lucid, and the economic arguments, while rigorously developed, are mostly based on straightforward logic and graphic analysis.

One of the principal arguments of the book remains that the externalities embodied in the discharge of waste materials can be internalized by effluent fees. These should be set at a level that will equalize the marginal costs of further waste reduction with the marginal downstream damages caused by the particular quantity of waste discharged. The authors build a strong case for effluent fees as being more conductive to efficient solutions to water quality problems than direct regulation of waste flows or public subsidies for treatment of wastes.

It is to the authors' credit that they do not gloss over the problems of setting effluent fees. These are several, but in this reviewer's opinion one of the more difficult occurs when there are non-linear or interdependent effects from the discharge of wastes. Here it would be difficult indeed to set effluent fees equal to marginal downstream damages, since the marginal damages would depend on the overall response to effluent fees and level of treatment by all waste dischargers. Similar is the case where the optimal level of collective water quality improvement measures, installed by a public authority, depends on the level of treatment that effluent fees elicit from individual waste dischargers, a problem that perhaps should have received more attention. It would seem that both of these problems suggest an approach in which waste reduction and effluent fees are negotiated between major waste dischargers and the public authority.

---

[1] Reviewed in this Journal by Irving Hoch in the November 1965 issue (47:1034–1036).

Despite these problems, the case for effluent fees is a strong one. As the authors recognize, it may not be possible to nicely balance the costs of waste abatement with the costs of waste discharge, but effluent fees would be a step in that direction as well as a source of public revenues.

It would be wrong to leave the impression that this book is merely an argument for adoption of effluent fees. It is a searching and well documented review of the multi-faceted aspects of water quality management and, like its predecessor, will have considerable impact on the thinking of economists, administrators, and policy makers in this field.

In *The Range of Choice in Water Management,* by Robert K. Davis, we have a challenging reconnaissance study. It is a good sequel to *Managing Water Quality* in that it shows by empirical study the direction in which we must go if we are to have rational water quality management. The book follows the path of systems analysis, employs computer simulation of water quality control works, and follows through with the broad institutional and political implications of the results.

As reported in the first part of the book, when the Corps of U. S. Army Engineers worked on a comprehensive plan for the Potomac in the late 1950 and early 1960 decades, the generally accepted means of water quality improvement were (and still are) treatment of waste effluents and augmentation of river flow during critical periods. Alternatives were considered but precluded, either because of costs, or, as in the case of pricing of water to limit use, because there was no clear authority for implementation.

In Part II, Davis focuses on the Potomac Estuary and the objective of maintaining dissolved oxygen at specified levels. First we learn that the vital model connecting waste discharge to oxygen level used by the engineers, though the best then available, has since been, in the author's view, superseded by a superior formulation. Next in this picture of fast breaking technology, several alternative methods of water quality control are introduced. A number of these are either in limited current use or in the experimental stage. Their costs were estimated by special engineering studies in support of the book. The costs of achieving 4 milligrams per liter dissolved oxygen is explored by systematically sampling the alternatives. These range from about 30 million dollars or less for systems relying on a combination of river flow augmentation, artificial reoxygenation of the estuary, and advanced waste treatment, to over 100 million dollars for the more costly alternatives among which are those that place sole reliance on flow augmentation and conventional waste effluent treatment. The general range of costs and ordering of systems by costs, while modified, is not drastically affected by changing from the earlier to the more recent model of dissolved oxygen levels. As would be expected, the marginal costs of successively higher oxygen levels are found to be much lower for the more economical control systems. Frequencies of system failures were reported for alternative reservoir capacities. The results (in addition to showing that the Corps plan held up quite well on this score, despite the use of a new dissolved oxygen model) give some insight into the costs of alternative goals when these are stated in frequencies of failure to achieve them.

This part of the book is buttressed by four well written and very candid appendices: one on water quality models, by Leo J. Hetling; the second on waste control processes, by Robert K. Davis; the third on reservoir system simulation, by Robert M. Steinberg; and the fourth on synthetic hydrology, by Nicholas C. Matalas. These are fine introductions for the technical student of the field. In both supporting materials and main text, a quality of freshness and excitement comes through to the reader. It is said in their praise rather than in their condemnation that these materials underscore how little we really know about this business and how vulnerable are the best assumptions. Despite this, it is this reviewer's judgment that the general orientation of the main conclusions hold up. There are promising new methods of water quality management and of systems analysis that deserve serious consideration.

Part III of the book summarizes the implications of the technical analysis. In the author's words, this comes to the problem of "widening the range of choice." It is suggested that a planning agency, rather than coming up with a complete plan as its first and final product, should first reconnoiter the costs of achieving alternative (and usually monetarily non-quantifiable) goals through a broad range of alternatives. Before the planning becomes committed to any approach, the more promising courses of action and kinds of authorities needed would be presented to public bodies. The choices would be narrowed and refined through successive iterations of interplay between the planners, the public, the researchers, and the operators of water systems. The final plea is for politicians in the best sense of the word—policy makers who will grasp the choices before them and make the decisions needed for rational planning.

Both books indicate how much further science has progressed in other fields related to water than in this area of policy and institutions.

Koo, Anthony Y. C., ***The Role of Land Reform in Economic Development: A Case Study of Taiwan***, **New York, Frederick A. Praeger Publishers, 1968, xvii – 197 pp. ($12.50)**

True to its title, this book is about the land reform experience of Taiwan and the role of that reform in Taiwan's economic development. After a brief review of the Japanese influence on Taiwan's development from 1895–1945, the author outlines the major steps in the land reform carried out during the period 1949–1953: farmland rent reduction, sale of public land, and land to the tiller. The relative income positions of operating farmers pre- and post-reform and the changes in agricultural productivity are analyzed. The author then attempts to measure (not too successfully in my view) intersectoral capital transfers and devotes one chapter to a discussion of unemployment in the farm sector and labor transfers from agriculture. In the final analytical chapter, the author looks in a general way at the direct costs and the opportunity costs of land reform.

The author concludes that the impact of land reform on Taiwan's economy was "both immediate and far reaching" (p. 123). Especially significant were increases in agricultural productivity which accompanied the reform. The author finds no evidence that land reform in the late 1940's competed significantly with industrial development. It "exerted little strain on the balance of payments. In short, the opportunity cost of land reform and agricultural development was minimal" (p. 124). In fact, "land reform contributed to the industrial development of Taiwan" (p. 124) through supply-demand interrelations, and especially through the "utilization of incremental income on the part of farmers to educate their children" (p. 124).

This is an informative book, but not an exciting one; it breaks no new ground. For the reader unacquainted with other literature on Taiwan's development and land reform, this work provides a useful overview of the process and an attempted economic evaluation of this experience. Yet, for my money, I'll take Raymond Christensen's 90-page USDA bulletin in preference to this $12.50 Praeger edition [1].

There are several troublesome, though minor, aspects. Readability would be much improved by a thorough editing. On page one, in the very first paragraph, the author states: "For example, in Thailand, India, and the Philippines, the agricultural population is 82.74, and 61 percent, respectively, of the economically active total in the 1960's." How shall we interpret such a statement? Careless wording (and/or omissions) of this kind and errors (e.g., p. 17, 67.2 percent should be 672 percent; pp. 78-79, the text refers to years 1914–19 but Table 20 refers to 1914–17; p. 103, the number 189 in Table 27 should be 191; etc.) detract from the analysis. One expects a more careful job in a book selling for $12.50.

But these are, after all, petty annoyances. The book has one major analytical problem, however. In Chapter 6, the author estimates the intersectoral flow of savings and concludes that "there was a flow of savings from the nonagricultural to the agricultural sector in the 1950's in Taiwan" (p. 87). "Direct contribution of agriculture to financing the growth of products of the nonagricultural sector was nil, if not negative, immediately following the land reform. . . . The net flow of surplus from the agricultural to the nonagricultural sector did not come about until in the late 1950's and early 1960's" (p. 90).

These statements contradict the findings reported by Christensen [1] based on work by T. H. Lee [2], and also the more recent work by Lee on these issues [3]. Since intersectoral transfer of capital is such a critical question in the theory of economic development, Lee's major conclusions are summarized here.

Lee's review covers the period 1895–1960. He distinguishes between financial, or visible, flows and invisible flows—the latter resulting from changes in the terms of trade. Financially, transfers through land rent payments and government taxation were most important in the pre-World War II period, while transfers in the form of farmers' savings became increasingly important in the post-war period. Conversely, invisible real net capital outflows brought about by terms of trade unfavorable to agriculture were less important in the pre-war period but accounted for more than 50 percent of the total outflow in the post-war years. Throughout the entire period, there was a net capital outflow from Taiwan's agricultural sector. The magnitude of this outflow showed a roughly increasing trend until near the end of the period [3, p. 40].

Why such contradictory conclusions? The major factor seems to be the exclusion or inclusion of transfers resulting from changes in the terms of trade between agricultural products and other products. Koo shows (p. 80) that the price index of agricultural products, relative to all commodities, dropped sharply in the decade 1951–60. "The fact suggests that the agricultural sector's contribution to the nonagricultural sector is more than that indicated by the amount of transfers estimated in the following sections of the present chapter" (p. 80). Yet he later ignores this caveat in drawing conclusions about net intersectoral capital transfers. Lee, on the other hand, points out that "In the post-war period . . . the contribution of real visible capital flow from agriculture to total capital formation was not large, but the real invisible capital outflow was large. The squeeze on agriculture through the low agricultural price policy was obviously great" [3, p. 37].

Koo's more restricted measure of capital flow is roughly consistent with the data on the same measure presented by Lee. But his failure to incorporate the terms of trade component leads to an erroneous conclusion with respect to *total* transfers.

Yet, in fairness to Mr. Koo, it must be noted that the analysis of intersectoral transfers is an extremely complicated undertaking—both conceptually and empirically. Thus, our judgment of his book should not hinge on this one question alone. I chose to highlight this issue because it seems to be central to the formulation of agricultural development policies.

Mellor, John W., Thomas F. Weaver, Uma J. Lele, and Sheldon R. Simon, ***Developing Rural India: Plan and Practice, Ithaca, Cornell University Press, 1968,*** **xxi + 441 pp. ($10.00)**

India is almost an unlimited source of data and experience in development. Its large area, diverse geographical characteristics, and enormous population, the great local variations in the social, cultural, and historical, as well as economic factors that affect development, and its obsession with documentation, all combine to present endless material for both case and more general studies from almost any point of view. The present book reflects, probably as well as a single fairly brief treatment can, the situation after fifteen years of Indian experimentation with planned development of agriculture. It is divided into five parts.

Part I (Mellor, 143 pages) summarizes the problems of agricultural development within the overall economic and historical situation and outlines quite effectively the objectives set by Indian planners, their successes and failures both in planning and implementation, and the status of agriculture at the end of the Third Five Year Plan in 1966. It presents also a brief, but essentially correct, survey of the lessons drawn from the 1951–1966 effort, leaving for Part V the recommendations for future activity based upon these lessons.

Part II (Weaver, 94 pages) goes in considerable depth into the production problems of rice and wheat farmers in Raipur District in Madhya Pradesh State. Since water is so basic a factor in rice production, he devotes considerable space to its management and to irrigation-system design. Against a brief historical background sketch, he outlines the evolution of land tenure and revenue, the caste system and its increasingly rapid breakdown, as well as its favorable and unfavorable implications for agricultural development, and summarizes weather, soils, and irrigation practices. He traces the history of the district as a fairly typical microcosm of India's approach to rice production as to land tenure, irrigation practices, water problems, research, and technological improvement, and stresses that social and cultural factors must be taken into account whenever technical production facilities and/or practices are to be changed. This was sharply demonstrated by the limited success of the Ford Foundation Package Plan for farm production improvement, which was applied to Raipur beginning in 1961. 1966 results indicate that local soil and climate factors reduced the effectiveness of new rice strains and cultivation methods and that traditionally evolved rice production techniques have many merits not previously appreciated by outsiders. Weaver brings into sharp focus the various elements of change required to improve production in Raipur, with implications that local factors may be of similar though varying importance in other parts of India. His analysis of water management needs in Chapter 10, and the summary in Chapter 11, are especially systematic and useful.

Part III (Lele, 60 pages) analyzes the traditional market structure for grain sorghum in the most important district, Sholapur, in Maharashtra State in West India; special attention is given to its effect on price spread, to the extent that it permits monopoly, and to ranges of and reasons for price variation. The study outlines very clearly the complex but well integrated wholesale and retail market operations in the district, finds and accounts for quite a high degree of competition at both levels, and explores the relations between market information, transportation and storage and speculation, among other factors, and price trends. This section might be improved by a summary, but brings together in a very compact, clear fashion what appear to be all the major factors at work in this market situation.

Part IV (Simon, 46 pages) describes a village, Senapur in northeast India, which is strongly affected economically by demand of the steel plant at nearby Bhilai both for labor and for agricultural products. Relations are traced between income levels and sources, between market development and consumption patterns, and agricultural production and investment. Here again no summary is provided, and a number of implicit conclusions are not clearly drawn—perhaps most important, that increase in agricultural output through heightened investment may be economically unjustified. However, to the extent that Senapur is typical, light is shed from new angles on these aspects of India's agricultural problems to round out usefully the descriptive and analytical parts of the book.

Part V (Mellor, 34 pages) lists problems, outlines prospects, and draws major lessons that emerge from the earlier four parts. Too brief for much detail, it nonetheless touches succinctly on key errors of the past and remedies needed for the future. There is room for skepticism regarding the annual 4.5 percent growth rate forecast for agricultural production; but the assumptions underlying it are clearly stated and can be evaluated one by one to arrive at a given reader's revised estimate. The list of errors may fail to consider adequately the built-in social, psychological, and organizational handicaps that impede the whole development program in India, remedies for which receive scant mention here. Some of the "lessons" are inevitably oversimplified. But these are quibbles.

The total thrust of the book is informative, thought-provoking and action oriented, and the comprehensive overview it affords of the agricultural development situation in India will prove valuable to anyone with a general interest in India or concerned with development of agriculture elsewhere.

The work is clarified by appropriate and well-prepared tables, illustrated by numerous clear and suitable graphs, and supported by one of the most complete, though still selective, bibliographies I have seen. Name and subject indexes, while limited, appear useful.

WILLIAM E. SCHENK
University of South Alabama

Papanek, Gustav F., ed., *Development Policy—Theory and Practice*, Cambridge, Harvard University Press, 1968, xvi + 367 pp. ($12.50)

The volume is an outgrowth of the practical technical assistance experience in six developing nations of the Harvard Development Advisory Service. It consists of a collection of eleven essays on various aspects of development planning and stabilization policy. The papers are fairly academic in style and content.

There are three papers which are econometric in nature (by Wouter Tims, by Alfred Conrad, and by Geoffrey Maynard and Willy Van Rijckeghem). Of these the most interesting is by Maynard and Van Rijckeghem who construct an econometric model to explain price level fluctuations. The Wouter Tims consistency I-O model for Pakistan, while undoubtedly carefully constructed and of great practical value to Pakistan's development planning, contains nothing new. After a cogent argument concerning the use of development models, the Conrad model for Liberia appears to be an afterthought. Two other papers, by Dunkerley and by Mallon, deal with exchange rate policy in Colombia and Argentina, respectively. Both are detailed analyses of specific exchange rate, tariff and subsidy arrangements and read much like IML or IBRD reports. The same is true of Bird's contribution on sales taxes in Colombia. The outstanding paper in the collection is that by David Felix on reasons for the failure of the import substitution policy in Latin America. It brings the best analytic tradition to bear upon an important empirical phenomenon, and shows that, far from being an unexpected result, the eventual exhaustion of import substitution as an engine of growth is inherent in the economics of the phenomenon. The substantive portion of the volume concludes with sectoral analyses, on Pakistanian agriculture by Falcon and Gotsch, and on wage policy in Liberia by Weckstein, and a retrospective by Papanek.

On the whole, the collection is rather disappointing. The by now standard two-gap model is the predominant theoretical framework underlying the analyses in this book. The empirical models are standard, too, and have been surpassed in other equally practical applications, for example, Eckaus and Parikh on India [1] and the papers on planning in the Adelman-Thorbecke volume [2]. If one is to judge by the present collection, the prolonged confrontation of well-trained academicians with the problems that arise in the course of policy formulation in developing countries has added very few new insights to the knowledge of development processes. This conclusion is reinforced by Papanek's essay in which he tries to address himself to the question: What have we learned from the fifteen years of practical involvement with development planning? Judging by Papanek's article, the answer appears to be a disappointing series of common-place generalizations.

President's National Advisory Commission on Rural Poverty, *Rural Poverty in the United States,* Washington, D.C., Government Printing Office, 1968, 601 pp. ($5.75)

This volume contains thirty-two background papers prepared for the President's Commission on Rural Poverty. Another eighteen unpublished papers are listed on the last page. The papers are grouped around the following subjects: Part I, Rural People and Their Communities; Part II, Mobility and Migration; Part III, Health and Family Planning; Part IV, Agriculture and Natural Resources; and Part V, Economics of Poverty.

Readers should not expect to find in this volume the substantive basis for all of the Commission's report, *The People Left Behind.* Only a few of these background papers were cited in the report, along with many other published sources. Much of the report also involves judgments and policy choices that are not subject to empirical validation.

The studies presented in this volume, however, are of scholarly interest in themselves. The staff directors, C. E. Bishop and George L. Wilber, are to be thanked for making these studies available in published form. Unfortunately, the "Table of Contents" lists the papers without naming the authors, many of whom are quite prominent in their fields.

Readers with widely different interests will find certain articles to be of special interest; therefore, only a lengthy summary could do this volume justice. In a brief space, any comments by this reviewer must be highly selective and personal.

The overall impression left by these studies, when closely compared with the report, is disturbing. Much of the work seems to have been done to count and describe the "people left behind." There is little analysis of causes that would suggest solutions to the problem of rural poverty. Most of the message that comes through is a generalized plea for a greater rural share of social welfare spending.

The article by Hyman P. Minsky, for example, pessimistically concludes that a full employment policy leads only to speculative over-investment causing inflation, while adequate monetary restraint must be accompanied by government support of employment as the employer-of-last-resort. This finding corresponds to the report's advocacy of some kind of federal job guarantee to accompany a universal minimum wage. Varden Fuller's article on hired farm labor also ends with a plea for minimum wages, although G. Edward Schuh's earlier article provides empirical estimates of the elasticities of demand and supply of farm labor. These suggest that minimums will frustrate more workers looking for jobs that are not there. The articles on health needs in rural areas suggest merely that more national supply of health manpower is needed, along with some construction of regional centers of rural health services. More credit and subsidy for rural housing, as well as a raising of welfare benefits for the elderly, are suggested to supplement rural living standards. James T. Bonnen's article shows that existing farm price support programs have not distributed benefits proportionately to low-income farmers; and even the defense of agricultural programs by Vernon C. McKee and Lee M. Day fails to show that the bulk of expenditures reduces interstate inequalities.

A thread of analysis of the labor market in a few articles, however, does seem to shed some light on needed public programs that might solve the problem. The articles by G. Edward Schuh and Rex F. Daly present the problem of slowly rising agricultural demand and rapid improvements in productivity. Several decades of high rural outmigration have reduced farm labor and population, but apparently not enough. Several descriptive articles reveal the resulting structure of low incomes: a high proportion of dependents (young and old), limited jobs for women, underemployment of males, and a deficiency of public facilities and services.

Why hasn't adjustment through outmigration provided a solution? The article by Dale E. Hathaway and Brian E. Perkins suggests how the "mobility process works less well for those who need it the most.' Mobility rates are lower for Negroes, older workers, small farm operators, low-income areas, and remote areas. Long-distance migration is mostly by the young and Southern Negroes, but there is little evidence that long distance pays greater dividends. More than 40 percent of those taking nonfarm jobs earned less in their first year, and with adverse earning experience they tend to return to farming. Return migration can amount to as much as 90 percent of outmigration.

What is needed to break out of this vicious cycle? The article by Donald Schon suggests that the greatest problem in initiating and directing migration is inadequate information on job opportunities. Then, housing shortages in urban areas cause much of the difficulty of urban assimilation. Previous inadequacy of education, several of the articles indicate, limits the urban job opportunities and earnings of rural migrants. The article by John F. Kain and Joseph J. Persky suggests that migration from rural areas only worsens the rural slums problems of major metropolitan areas; so they advocate more industrial development in the rural South. Hathaway and Perkins also suggest that most persons who leave farming take local jobs, if available, and that they fare better when near large cities.

All of this suggests a priority for public policies of subsidy to rural areas in education and industrial development. Kain and Persky warn that equal opportunity for Negroes must accompany aid to education and job development; and they argue that, contrary to E.D.A. policy, new industry should be allowed to seek the most efficient locations within the region. Anne O. Krueger's article, in fact, shows faster-than-average urban growth in cities with over 50,000 population. And Wilbur R. Maki's article suggests that public investments in community infra-structure is only a necessary, not a sufficient, condition of industrial growth.

JOHN M. PETERSON
Arkansas Employment Security Division

Schultz, Theodore W., *Economic Growth and Agriculture*, New York, McGraw-Hill, 1968, x + 306 pp. ($9.95)

This book would have been better titled "Selected Essays by Theodore Schultz on the Economic Development of Agriculture." It is an uneven collection of 32 items that appeared from 1956 to 1967, ranging from book reviews and discussants' comments of conference papers on the one hand, to journal articles and chapters from books on the other. (A little over half are as recent as 1966 and 1967.) They all deal with some facet (or facets) of economic growth in the agricultural sector, but as a group they conspicuously neglect the relationships between the agricultural sector and other sectors, and what ground they do cover is not covered systematically.

It is a worthwhile book if for no other reason than that it makes readily available a number of widely scattered items, many of which originally appeared in relatively inaccessable publications. But—probably because many of the contributions were originally conference papers or statements made to policy makers—this volume is rarely Schultz at his best. The bulk of the papers are more provocative than convincing; they often do not fit well together; there is considerable overlapping; there is at times confusion between conditions and problems of agriculture in developed and developing countries; and discussion of specific developing economies is limited mainly to two countries in Latin America, Chile and Mexico.

Schultz writes well, but to forge a chapter simply by hinging together two or more papers written at different times for different audiences makes for tedious reading. For example, the bulk of Chapter 3 is on land as a factor of production but shifts abruptly, without warning or explanation, into two pages that originally appeared as Schultz's side of a debate with C. V. Plath. Here, as elsewhere, when portions of a debate are reprinted, the effect is like overhearing a phone convrsation—the reader gets only Schultz's half of the argument. It would have been helpful to have the other half also reproduced—perhaps in an appendix. The chapter ends with what was originally a review of Ester Boserup's *The Conditions of Agricultural Growth* (London, 1965), presented without any attempt to say how it relates to the preceding debate with Plath or the other topics in the chapter.

Chapers 2 and 4 both deal with population. Chapters 2, 4, 5, 6, 8, 10, and 11 deal largely with the United States and focus mainly on poverty, human capital, and agricultural research. Chapter 9 touches on selected aspects of agricultural development in Latin America. Chapter 12 is Schultz's criticism of two papers on theory related to agricultural growth, one by John Mellor and the other by Kazushi Ohkawa. Neither paper is reprinted, and because Schultz sometimes fails to spell out clearly the positions with which he is taking issue, it is impossible to make sense of much of what he has to say without a trip to the library.

The reader who can force himself to wade through the repetition will find a good deal of food for thought but will be frequently distracted by a carelessness in presentation of evidence that is at times unforgivable. Schultz quotes W. Arthur Lewis on the lack of response of African farmers to economic incentives and correctly criticizes him (p. 5) without a hint as to which of Lewis' voluminous and far flung writings the quote is from—and without citing any of the evidence that is damaging to Lewis' position. At other points, without bothering to show a shred of evidence, Schultz boldly asserts that in the years ahead "the endowment of natural resources in most countries will not prove to be a limitational factor to large increases in agricultural production" (p. 7); that "countries producing food grains, predominantly wheat and rice, for export will see the demand for such exports weaken substantially from what it has been in recent years" (p. 8); and that, in developing countries, we have "started with extension programs before there was anything worthwhile to extend to farmers" (p. 13). In discussing problems of developing countries, he makes international comparisons of levels of living in Latin America without explaining the criterion (or criteria) for placing a country in the "very poor" group as opposed to "not nearly so poor" or "comparatively well to do" (pp. 193–94). Yet he asserts, without qualification, that the "very poor" are "about as poor as countries anywhere" (p. 194).

Some of the contributions are excellent throughout. The last half of Chapter 7 is his paper on efficient allocation of scientists presented at the 1967 meetings of the American Agricultural Economics Association at Guelph and is carefully reasoned, with penetrating insights. Chapter 8, devoted to human capital, is an important contribution in an area where his pioneering work has done much to change some of our concepts about the process of economic development.

There is an index, but it is woefully inadequate, being not nearly detailed enough and completely failing to list a number of important topics that show up in the text (e.g., terms of trade, pp. 13, 15, and 101; disguised unemployment, pp. 202–205; supply response of farmers, pp. 13, 34, 39, and 220; and agricultural surpluses, pp. 23 and 25).

Although disappointingly marred in places by carelessness and the way in which they were packaged, a number of the papers in this collection are stimulating and still timely. We can be grateful that we now have them together under hard cover.

MARVIN P. MIRACLE
University of Wisconsin and Indiana University

Trant, Gerald I., David L. MacFarlane, and Lewis A. Fischer, *Trade Liberalization and Canadian Agriculture*, Toronto, University of Toronto Press, 1968, 119 pp. ($3.50)

In 1965 the Private Planning Association of Canada initiated a series of studies to explore the implications to Canada of trade liberalization among the nations bordering on the North Atlantic. Of about a dozen publications covering six major sectors and a number of policy considerations, one publication was devoted to agriculture. This volume consists of two monographs written quite independently by G. I. Trant and by MacFarlane and Fischer.

Trant's 68-page study, "The impact of trade liberalization on Canadian agriculture," examines the likely effects on the production, trade, and prices of almost all Canadian farm products if barriers to trade were to be eliminated among the countries bordering on the North Atlantic. Although not specifically stated by the author, he seems to have assumed also that certain government subsidies and controls would be reduced. Thus, he posits relaxation of production controls on tobacco in Canada and the United States and elimination of the Canadian subsidy on sugar beets, but he is not explicit about such vital assumptions as the maintenance of the wheat acreage allotment program in the United States or deficiency payments programs in any of the countries discussed. He does make a blanket and very vague assumption (p. 1) "that intranational institutional arrangements will remain relatively unchanged," but what this means in the case of individual commodities is unclear.

Trant's theoretical concepts provide a second problem for the reader. He confuses comparative advantage and absolute advantage in his introduction, citing a more rapid increase in "agricultural productivity" in Canada than in the United States as evidence that "Canada's comparative advantage in agriculture has improved relative to that of the United States . . ." (p. 5). Absolute advantage is sometimes found by comparing current farm price levels in different countries and sometimes by estimating opportunity costs in Canada but not in other countries.

In spite of these serious criticisms, the main body of Trant's study provides a remarkable concentration of well-chosen data, institutional and policy descriptions, and insight. This study would make useful introductory reading for anyone concerned with Canadian agriculture and policy, especially on a commodity-by-commodity basis.

The second monograph "Prospects for trade liberalization in agriculture," by MacFarlane and Fischer, is a 50-page rather discursive discussion of agricultural policies and developments in North Atlantic countries. The authors differ with Trant, maintaining that "Canada's comparative-advantage position has clearly worsened over the past ten years" (p. 113), giving as sole proof what they call "the most striking evidence" that Canada is now in an agricultural trade deficit position vis-à-vis the United States.

A criticism common to both papers is that they have attempted far too much, but Trant's well documented treatment of every major farm commodity produced in Canada will remain a useful first reference for some time.

D. R. CAMPBELL
University of Toronto

Williams, D. B., ed., *Agriculture in the Australian Economy*, Sydney, Sydney University Press, 1967, xvii + 349 pp. ($6.00)

These essays were distributed to conferees of the International Association of Agricultural Economists at its 13th conference, held in Sydney, New South Wales, Australia, in 1967. They are designed to acquaint the reader with principal features of Australian agriculture, together with its opportunities and problems, past, present and future. This purpose is accomplished in a manner to attract wide readership among the many interested in this fascinating corner of the world. The collection is well balanced in terms of relevant topics and displays the considerable talent available in the community of Australian agricultural economists. Yet the volume seldom is so technical as to tax even the most general reader.

That development is the name of the game in Australia is revealed by the content of the volume to a greater extent than may have been intended by the individual contributors. The time path of development—past, contemporary, and future—is related by Shaw, Hooke, and Hoffman, respectively. Ecological influences on development are described by Davidson and Donald in terms, respectively, of land-use response to climate and markets and of innovational adaptations to the Australian physical environment. Many Americans in Canada and the United States feel a cultural kinship with Australians. These chapters will help to explain differences in development patterns and current structure.

Nor is the organizational infrastructure overlooked. Druce outlines the organization of research, education, and public service facilities, relating them to the political organization of the country. We are reminded here of Australia's youth as a nation. The colonies were federated into the present six states (and a Commonwealth territory) in 1901. Chislett outlines the impressive array of organizations founded in its brief history to represent groups of farmers and graziers. Many in Canada and the United States will recognize the tendencies to group around commodity and other interest groups.

Essentially the same size as continental United States, Australia contains but slightly more than 11 million persons. However, it is among the most urbanized countries of the world—and among the most isolated. Hence the relation of markets to development is of special importance. Sixty percent of Australia's agricultural production is exported, contributing three-fourths of Australia's foreign exchange. Over 90 percent of Australian wool is exported, accounting for half the wool in world trade. Australia is second only to the United States in agricultural exports and is 13th in terms of total exports.

McKay and Harris outline current problems in Australia's world trade, discussing current changes in relations with trading partners, with appropriate emphasis on the United Kingdom, United States, and Japan. Competent discussions of supply and demand for Australian farm products are provided by Gruen, Ward, and Powell, and by Gruen and McLaren. In the latter, Australian diets are compared with those of other selected countries. Parish outlines and analyzes the marketing methods and instruments evolved to counter marketing peculiarities generated by the Australian environment.

Resource endowments and policies related to their use are discussed by Campbell (land), Schapper (labor), Jarrett (capital and credit) and Lewis (price policies). Australian agriculture is featured by extensive use of land, by capital intensity, and by high cost of labor. On the whole, farms are large in physical size and produce incomes essentially equal to non-farm incomes on the average, though they vary substantially more over time than do non-farm incomes. Income disparities are found (e.g. in small-farm dairying) but are relatively rare compared with most other advanced countries.

Minor complaints might be made. Despite the heavy emphasis given development, little analytic treatment is provided to relate agricultural growth processes to national economic growth. Nor are there references to imaginative uses, available in Australian literature, of input-output models. These would have helped remedy a general deficiency in intersector analysis. To encourage investment, and hence growth, capital gains are exempted from Australian taxation. Analysis of the allocative and equity effects, comparable (say) with Parish's analysis of market instruments, would have been a useful addition.

The visitor to Australia invariably is impressed with two features: the world's oldest landscape and the oldest surviving human population. The former is reflected abuntantly in the volume. The latter receives but two brief mentions: Davidson notes that aborigines comprise over half the labor force on cattle stations of the Northern Territory and Western Australia, and Donald comments on the fact that none of the plants and animals collected and hunted by aborigines has yet been found useful in domesticated species. (They don't survive competition with introduced species in the presence of enriched fertilizer and feeding regimes.) It would have been especially interesting had Professor Schapper shared some of his observations on problems related to aborigines.

But these *are* minor complaints. The volume is a useful one and deserves a wide readership among the many interested in Australia. A warning: it may induce in the reader still a greater wanderlust in the direction of this South Pacific "island continent." However, should the bug really attack, the traveler could scarcely find, in such short compass, a more competent introduction to economic aspects of Australian agriculture. It is a useful complement to several excellent geographical, geological, and historical accounts that are already available.

Announcements

WINTER MEETING
AMERICAN AGRICULTURAL ECONOMICS ASSOCIATION WITH ALLIED SOCIAL SCIENCE ASSOCIATIONS

December 27–30, 1969, New York

The winter meeting of the American Agricultural Economics Association will be held in conjunction with the Allied Social Science meetings in New York City, December 27–30, 1969.

The program is as follows:

Sunday, December 28	
Macro-Simulation Models	Chairman, George Judge, University of Illinois (Joint program with Econometrics Society)
Monday, December 29	
Current Economic Policy—Its Appropriateness and Effectiveness—A panel discussion with audience participation	Panel: Walter Heller, Department of Economics, University of Minnesota; Henry Wallich, Department of Economics, Yale University; John Schnittker, Department of Economics, Kansas State University; D. Gale Johnson, Department of Economics, University of Chicago (Joint Session with American Economics Association)
Monday, December 29	
AAEA Luncheon	Members are urged to get tickets to this event immediately upon their arrival.
Tuesday, December 30	
Meeting the Changing Need for Agricultural Statistics	Chairman, Joseph Ackerman, Farm Foundation Participants to be announced.

1970 ANNUAL MEETING

The 1970 annual meeting of the American Agricultural Economics Association will be held in Columbia, Missouri, August 9-12, 1970. The meeting will be a week earlier than usual to avoid conflict with the meeting of the International Association of Agricultural Economists. Please send program suggestions to Dale E. Hathway, Department of Agricultural Economics, Michigan State University, East Lansing, Michigan.

JOURNAL OF LEISURE RESEARCH

The National Recreation and Park Association announces publication of the *Journal of Leisure Research,* a new venture launched in response to a pressing need for the communication of comprehensive information on leisure research. To be published quarterly, beginning with Winter (January) 1969, the Journal will disseminate research findings in the social and natural sciences related to leisure. It is conceived as an interdisciplinary research reference to alert professionals to innovative research methods and significant data to meet the challenges of the future and will reflect consideration of the multitudinous forces that influence leisure trends and behavior patterns. Contributions are encouraged from researchers engaged in relevant studies. Scholarly articles, research notes, book reviews, and communications are welcomed for publication review. Address manuscripts, correspondence, and subscription inquiries to the Editor, *Journal of Leisure Research,* National Recreation and Park Association, 1700 Pennsylvania Avenue, N.W., Washington, D.C. 20006.

AAEA DUES

Dues for 1969 are payable. The dues rates are as follows:

Regular membership	$10.00
Junior membership (graduate students, 3-year maximum)	5.00

Please mail your check, payable to the American Agricultural Economics Association or AAEA, to C. D. Kearl, Secretary-Treasurer, AAEA, Department of Agricultural Economics, Cornell University, Ithaca, New York 14850.

WESTERN AGRICULTURAL ECONOMICS ASSOCIATION

The annual dues rates are as follows:

Regular membership	$3.50
Student membership (with student status certified by department)	1.00

Mail application and check to Leo R. Gray, Secretary-Treasurer, WAEA, Post Office Box 89, Berkeley, California 94701

SOUTHERN AGRICULTURAL ECONOMICS ASSOCIATION

Annual membership dues (includes proceedings issue of *SJAE*)	$3.00

Direct correspondence concerning membership to John C. Redman, Secretary-Treasurer, SAEA, Department of Agricultural Economics, University of Kentucky, Lexington, Kentucky 40506.

CANADIAN AGRICULTURAL ECONOMICS SOCIETY

Annual membership fees	(Can.) $10.00

Mail fees to Treasurer, CAES, Box 632, Postal Station B, Ottawa, Ontario, Canada.

News Notes

CORNELL UNIVERSITY

APPOINTMENT: **Timothy D. Mount**, assistant professor.

LEAVES: **D. J. Allee**, Systems Analysis Group of the Special Assistant for Civil Functions, Office of the Secretary of the Army; **D. G. Sisler**, Yale University Growth Center (one year).

AWARDS: **L. C. Cunningham**, Professor Emeritus, Agricultural Counselor Award, Farm Credit Banks of Springfield, Massachusetts, and Fulbright Lectureship, University of West Indies, Trinidad (one year).

ECONOMIC RESEARCH SERVICE, USDA

(C&MS is Consumer and Marketing Service; ESAD is Economic and Statistical Analysis Division; FDTD is Foreign Development and Trade Division; FPED is Farm Production Economics Division; MED is Marketing Economics Division; OECD is Organization for Economic Cooperation and Development; NRED is Natural Resources Economics Division; TSAB is Trade Statistics and Analysis Branch.)

APPOINTMENTS: **L. Jay Atkinson**, acting chief, Economic Development Branch, FDTD, after return from 2-year assignment in Colombia; **John R. Brooker**, MED, Gainesville, Florida; **Charles Handy**, Ph.D. Cornell, MED, Washington, D.C.; **David N. Harrington**, FPED, Washington, D.C.; **Arthur B. Mackie**, formerly of Economic Development Branch, FDTD, acting chief, TSAB; **D. C. Myrick**, formerly assistant to Director, FDTD, coordinator of newly formed Foreign Programs Group in Office of Director, FDTD; **Robert E. Oehlschleager**, FPED, Pullman, Washington; **Jerald O'Mara**, MED, Raleigh, North Carolina; **Bushra Abdel Sayed**, Ph.D. Michigan State, NRED.

TRANSFERS: **Robert F. Boxley**, NRED, from Michigan State University to Washington, D.C.; **William D. Givan**, FPED, from Blacksburg, Virginia, to Athens, Georgia; **Vernon Grise**, FPED, from Lexington, Kentucky, to Washington, D.C.; **Donald S. Kuryloski**, from ESAD, head of Vegetable Section, Commodity Analysis Branch, to C&MS, head of Vegetable Branch, Fruit and Vegetable Division; **Glenn A. Zepp**, FPED, from Storrs to Washington, D.C.

LEAVES: **Reed Hertford**, FDTD, returned from 3-year research assignment in Mexico; **Sheldon Williams**, MED, Champaign, Illinois, 2-year assignment in India.

RESIGNATIONS: **Nicholas Filippello**, FDTD, to McDonnell Automation Company, St. Louis, Missouri, as economic consultant; **Tom Full**, FDTD, to OECD, Paris; **Glenn H. Glover**, FPED, to Cotton Producers Association, Atlanta, Georgia; **Edgar L. Michalson**, FPED, Pullman, Washington, to

University of Idaho; **Robert L. Tontz**, chief of Trade Statistics and Analysis Branch, to Director of Marketing Economics Division, OECD, Paris.

RETIREMENT: **Erling Hole**, FPED, after 33 years of Federal service.

UNIVERSITY OF FLORIDA

APPOINTMENTS: **Leo Polopolous**, formerly research economist with Florida Citrus Commission, professor; **Kenneth C. Gibbs**, **John Holt**, **Anthony A. Prato**, and **William Kary Mathis**, assistant professors.

LEAVE: James E. Ross, formerly Chief of Party with University of Florida-AID in Costa Rica, Contract Coordinator, University of Florida-AID, Ghana.

UNIVERSITY OF ILLINOIS

APPOINTMENTS: **Roland R. Renne**, formerly Director, Office of Water Resources Research, Department of the Interior, professor and Associate Dean of the College of Agriculture and assigned to Uttar Pradesh Agricultural University, Pant Nagar, India, as Chief of Party; **Bruce L. Brooks** (returned from Jawaharlal Nehru Agricultural University, Jabalpur, India), professor; **Robert W. Herdt** and **Earl D. Kellogg**, assistant professors.

LEAVES: **T. A. Hieronymus**, sabbatical (one year); **R. J. Mutti**, sabbatical (6 months).

OKLAHOMA STATE UNIVERSITY

APPOINTMENT: **Paul D. Hummer**, assistant professor.

AWARDS: **Wayne D. Purcell**, Outstanding Teacher in the College of Agriculture in OSU Alumni-Blue Key 1969 Award competition; **John W. Goodwin**, OSU Alpha Zeta Outstanding Teacher Award, 1968–69.

SOUTH DAKOTA STATE UNIVERSITY

APPOINTMENTS: **Max Myers**, formerly head of the Economics Department and administrator of Foreign Agricultural Services, Director of the Institute of Social Sciences for Rural-Urban Research and Planning; **John E. Thompson** is now head of the department; **Raymond O. Gaarder**, formerly Director of Research with the Livestock Producers Association, Chicago, Livestock Marketing Specialist in the Economics Department.

WASHINGTON STATE UNIVERSITY

APPOINTMENTS: **Donald A. West**, Ph.D. Wisconsin, assistant professor; **Roland C. Bevan**, formerly of University of Idaho, and **Joseph G. Hattersley**, research associates; **Eleanor S. Hungate**, formerly of University of Alaska, research assistant.

LEAVE: **Paul W. Barkley**, visiting professor, University of California, Berkeley.

UNIVERSITY OF WISCONSIN

APPOINTMENTS: **Peter G. Helmberger**, formerly of University of California, Berkeley, professor; **Daniel W. Bromley**, Ph.D. Oregon State, assistant professor.

LEAVE: **Bernard L. Erven**, returned after 3½ years with Wisconsin Project, Federal University of Rio Grande do Sul, Porto Alegre, Brazil.

UNIVERSITY OF WYOMING

APPOINTMENTS: **Thomas L. Dobbs**, Ph.D. Maryland, assistant professor; **R. Burke Teichert**, instructor.

OTHER APPOINTMENTS

E. J. Battison, Ph.D. Pennsylvania State, senior resource analyst, Research Management Corporation, Washington, D.C.

Christoph Beringer, formerly with Development Department, OECD, Paris, "Agrar- und Hydrotechnik GmbH," Consulting Engineers, Essen, Germany.

Lon C. Cesal, formerly of Iowa State University, Ford Foundation, Brazil.

Dean T. Chen, Corporate Planning Services, Deere & Co., visiting associate agricultural economist, University of California, Berkeley.

T. K. Cowden, formerly Dean of Agriculture, Michigan State University, Assistant Secretary of Agriculture.

Stanley G. Detering, lecturer in resource economics, University of Nevada.

Chennat Gopalakrishnan, formerly of Montana State University, associate professor, University of Hawaii.

James R. Kendall, formerly head, Food and Feed Grains Section, Agricultural Estimates Division, SRS, deputy director of the division.

Oscar E. Mazuera, Ph.D. Oklahoma State, Agricultural Program Advisor to Cauca Valley Corporation of Development, Colombia.

Wendell M. McMillan, FAO, Programme Manager, PACCA (Programme on Agricultural Credit and Cooperatives in Afghanistan), Kabul, Afghanistan.

Byron D. Oliver, Ph.D. Cornell, operations research staff, National Cash Register, Dayton, Ohio.

Glen R. Purnell (president, CAES), formerly of University of Alberta, Director-General, Economics Branch, Canada Department of Agriculture, Ottawa.

Terry L. Roe, Ph.D. Purdue, assistant professor, University of Minnesota, and agricultural economist, ERS, USDA.

Sujit K. Roy, Ph.D. Pennsylvania State, assistant professor, Texas Technological College.

William Schott, M.S. Michigan State, Central Computing Inc., Lubbock, Texas.

Philip J. Thair, head of department, University of Saskatchewan.

Clifton R. Wharton, Jr. (AAEA director), vice-president, Agricultural Development Council, elected a director of Equitable Life Assurance Society of the U.S.

OTHER LEAVES

Gian S. Sahota, Vanderbilt University, academic visitor, London School of Economics and Political Science (May-Sept. 1969).

OTHER RETIREMENTS

Geoffrey Shepherd, professor of economics, Iowa State University, May 31, 1969.

OTHER AWARDS

James G. Kendrick, 1969 Distinguished Teaching Award, University of Nebraska.

OBITUARIES

Harold Abel, coordinator of Western Livestock Marketing Research since 1947, died in Denver on February 16, 1969, following a heart attack. He was born May 9, 1910, in Lincoln, Nebraska, and is survived by his wife. Harold received his Bachelor of Science degree from the University of Wyoming in 1934. He was first employed by the U.S. Department of Agriculture in 1930 in Wyoming in the Agricultural Estimates Division. In 1938 he transferred to Cheyenne with the Bureau of Agricultural Economics; then, in September, 1947, to Denver to be Coordinator of Western Livestock Marketing Research. In the following years, he was to contribute as much as any single individual toward making regional research in the West a working concept. The office of the regional coordinator in Denver gave continuity and direction to technical committee activities. Workers in experiment stations throughout the Western states will remember the help that this kindly, patient man gave them in getting started in their research and teaching.

Eric R. Berg, professor of agricultural economics at the University of Alberta, died in Edmonton, Alberta, on March 15, 1969, at the age of 48. A native of Fredericksburg, Texas, Professor Berg received the Bachelor of Arts and Master of Arts degrees from the University of Texas and the Master of Science and the Doctor of Philosophy degrees from the University of Illinois. He served in the United States Navy during the Second World War and the Korean War.

Dr. Berg was employed by the U.S. Department of Agriculture from 1959 to 1962 as assistant branch chief and acting branch chief in the Regional Analysis Division of the Economic Research Service. Following his appointment at the University of Alberta in 1962, Professor Berg contributed substantially to the growth and development of the Department of Agricultural Economics. He was an outstanding teacher and an internationally distinguished authority on world trade and futures trading. His research work included fundamental studies in trade patterns and price behavior. Plans are being made for an Eric R. Berg Memorial Fund at the University of Alberta.

Grady B. Crowe, assistant to the chief, Production Adjustments Branch, FPED, ERS, Washington, D.C., died on April 26, 1969. Death was attributed to a massive coronary thrombosis. Dr. Crowe was born in Athens,, Ga. He received the B.S.A. degree from the University of Georgia in 1938 and the Ph.D. degree from the University of Virginia in 1950. Most of his professional career was spent at the Delta Branch Experiment Station in Stoneville, Mississippi, where he was engaged in research and research administration with FPED and its predecessor agencies. During his 20 years at Stoneville, he gained national recognition as an outstanding authority on the economics of cotton production. In 1953, he received a superior service award from the USDA for meritorious research on economic problems of cotton mechanization. During World War II, he served with the 18th Infantry, First Division in Central Europe. He was a member of Phi Kappa Phi and the American Agricultural Economics Association.

Eric Englund, 76, retired foreign service officer and former Department of Agriculture official, died in February after a long illness.

Born in Sweden, he came to the United States at the age of 14 and became a naturalized citizen in 1917. He was graduated from Oregon State College in 1925. Englund also received an M.S. degree in agricultural economics from the University of Wisconsin and a doctorate in economics from Harvard University in 1936.

Beginning in 1926, he held various positions with the Department of Agriculture, including branch chief of the Office of Foreign Agricultural Relations, from 1942 to 1946. Following his appointment as agricultural attache in the Foreign Service in 1946, he was assigned to Stockholm and Helsinki. In 1950, he was appointed assistant director of foreign agricultural relations for the Department of Agriculture. Mr. Englund then served as agricultural attache to London from 1952 to 1958, shortly before his retirement.

He was made a Knight of the Royal Order of the North Star by King Gustaf of Sweden in 1950 and received the Distinguished Service Award from the Department of Agriculture in 1957. He was a past president of the American Farm Economic Association and a member of the Swedish Academy of Agriculture.

He is survived by his wife, Gladys.

Albert R. Graf, MED, ERS, cereal grain specialist, died on April 20, 1969. He retired from MED in 1968.

Gabriel Lundy, head of the agricultural economics department at South Dakota State University from 1936 to 1949, died on November 2, 1968, following an automobile accident. He pioneered the early development and growth of the economics department.

Henry C. Taylor, 96, acknowledged as the "father of agricultural economics," died at Sibley Memorial Hospital, Washington, D.C., April 28, 1969, following a lengthy illness.

Dr. Taylor's career in agricultural economics spanned more than 60 years and included authorship of the first agricultural economics textbook in 1905. Dr. Taylor also helped to establish the first department of agricultural economics in the United States at the University of Wisconsin. He spearheaded the organization of the Farm Management Association, later known as the American Farm Economics Association, which he served as fellow and president in 1920. He was a life member of the Agricultural History Society and served as its president in 1936.

"Henry Taylor knows, as few men know, to what extent the agriculture of the world is a common concern of every people," wrote W. E. Hocking in his book, *The Lasting Elements of Individualism.*

Dr. Taylor was born at Stockton, Iowa, in 1873 and received his Bachelor of Agriculture degree in 1896 from Iowa State College. His master's degree was earned in 1898, also at Iowa, and his doctorate from the University of Wisconsin in 1902.

Dr. Taylor's capabilities in agricultural economics and rural sociology earned him the chairmanship of the Agricultural Economics Department at Wisconsin in 1909, a position he retained until 1919. He was affectionately dubbed "Agrostis" (*agrostis alba,* the botanical name for redtop) by his students.

Dr. Taylor moved to the U.S. Department of Agriculture in Washington, D.C., in 1919. During the next half dozen years he headed the Office of Farm Management and Farm Economics and the Bureau of Markets and Crop Estimates and was the organizer and first head of the Bureau of Agricultural Economics. In 1925 he left the Department for Northwestern University and its Institute for Research in Land Economics.

During Dr. Taylor's career he served as director of the survey of rural Vermont, 1928-1931; in Rome on the Permanent Committee of the International Institute of Agriculture, 1933-1935, and as the President of the Institute's 13th General Assembly in 1936. He was managing director of the Farm Foundation of Chicago from 1935 to 1945 and then again came to Washington, D.C. as agricultural economist for the Foundation until 1952.

Dr. Taylor's many writings include these books: *Introduction to Agricultural Economics, Outline of Agricultural Economics,* co-author of *World Trade in Agricultural Products,* and *The Story of Agricultural Economics,* written with his late wife, Anne Dewees Taylor. At the time of his death, a book on the Iowa farm which had been in the family for over one hundred years, was in press.

A daughter, Esther E. Taylor, of Washington, survives.

Hadley Van Vliet, professor and head of the Department of Agricultural Economics, University of Saskatchewan, Canada, died suddenly on December 8, 1968. Born in Saskatchewan in 1914, he received B.S.A. and M.Sc. degrees in agricultural economics from the University of Saskatchewan in 1934 and 1936, with many honors. He had completed most of the work for the Ph.D. degree at the University of Wisconsin in 1938, when he joined the department at the University of Saskatchewan. He was head of the department continuously since 1944. Widely known throughout the United States and Canada as a brilliant mind and fluent speaker, he was likewise recognized for his skill, devotion, and energy in teaching, research, extension, and public service. A Memorial Fund has been established to make awards for graduate study and scholarly work in agricultural economics. Brochures will be sent on request and contributions will be gratefully received. The address is Hadley Van Vliet Memorial Fund, Box 500, Sub. P.O. No. 6, Saskatoon, Saskatchewan, Canada.

AGRICULTURAL PLANNING ECONOMISTS DEVELOPMENT APPRAISAL ECONOMISTS

are sought by the Food and Agriculture Organization of the United Nations (FAO) for present and projected vacancies in developing countries throughout the world.

Posts vary from three months to two years or longer.

IF YOU HAVE:

- —appropriate university degree
- —substantial experience in economic development planning, agricultural development project appraisal
- —working knowledge of English, French or Spanish

WE CAN OFFER:

- —liberal emoluments based on depth and breadth of training and experience
- —generous fringe benefits

Send a brief resumé to: Chief, Recruitment Section, FAO, Viale delle Terme di Caracalla, Rome, Italy, quoting Ref. 264/EA/35/JFE.

Application forms and detailed vacancy announcement will be forwarded to apparently qualified individuals.

AGRICULTURAL DEVELOPMENT OF TAIWAN, 1903–1960

By Yhi-Min Ho. "Taiwan's agricultural economy since the beginning of the 20th century has shown a remarkable propensity for growth. In this highly technical, yet clearly organized study, Professor Ho seeks to define the parameters of agricultural growth and also attempts to assess the Taiwan experience in light of some commonly employed general theories of economic development. A valuable addition to the literature on agricultural development." —*Journal of Developing Areas*

"An excellent book. Most valuable is the theoretical and statistical methodology used to isolate and identify sources of residual [agricultural growth]." —*Choice*

Notes: University Schools of Business

The JOURNAL OF BUSINESS is published quarterly by the University of Chicago Press. Subscriptions are $8.00 per year (individual) and $12.00 per year (institutional) and should be addressed to the University of Chicago Press, 5750 South Ellis Avenue, Chicago, Illinois 60637. Manuscripts in duplicate, typed and double-spaced (including footnotes and quotations), and editorial correspondence should be addressed to Irving Schweiger, Editor, JOURNAL OF BUSINESS, Graduate School of Business, Haskell Hall, University of Chicago, Chicago, Illinois 60637.

LAND ECONOMICS

A QUARTERLY JOURNAL DEVOTED TO THE STUDY OF ECONOMIC AND SOCIAL INSTITUTIONS

Founded in 1925 at The University of Wisconsin

This magazine exists to provide an outlet for a wide variety of scholarly studies in land economics. It reflects the growing emphasis on planning for the wise use of urban and rural land to meet the needs of an expanding population. Housing, air and water use, and land reform are within its scope. It views land economics as economics in the broadest sense with particular emphasis on public action to achieve the best use of resources in the public interest.

Annual Subscription $8. Life Subscription (Individuals only) $100. Single copies $2.50

Correspondence concerning information regarding submission of manuscripts, permission to reprint, and other editorial matters should be addressed to: Mary Amend Lescohier, Editor, Social Science Building, University of Wisconsin, Madison, Wisconsin 53706.

Subscription orders should be sent to:
Journals Department. The University of Wisconsin Press. Box 1379. Madison, Wisconsin 53701

WORLD AGRICULTURAL ECONOMICS and RURAL SOCIOLOGY ABSTRACTS

(W A E R S A)

is the ONLY comprehensive source of information on a world scale covering all significant publications on International, Regional and National aspects of

Agricultural Policy
Trade, Marketing and Prices
Finance and Credit
Production Economics
Co-operation
Education and Training
Rural Sociology
Research Methods and Techniques and Related Topics

Each quarterly number includes over 1,000 classified and indexed abstracts. Review articles which include comprehensive bibliographies have so far dealt with: Production Function Analysis; Marketing Poultry Meat; Part-time Farming; Agriculture in Centrally Planned Economies; Measurement of Productivity in Soviet Agriculture; The Adoption and Diffusion of Agricultural Practices; The Evaluation of Extra-Market Benefits; The Growth of Work Study and Allied Techniques in Agriculture.

Heavy subsidies contributed by Governments of the British Commonwealth and the Republic of Ireland reduce the annual subscriptions well below cost.

Contributing Countries £4 10s.

Non-contributing Countries £7 10s. ($19.50)

Produced quarterly by the:
COMMONWEALTH BUREAU OF
AGRICULTURAL ECONOMICS
31A St. Giles, Oxford.

Orders and Subscriptions to:

EDITORIAL COMMUNICATIONS

Editorial communications, including manuscripts submitted for publication or inquiries concerning the JOURNAL, should be addressed to Varden Fuller, Department of Agricultural Economics, University of California, Berkeley, California 94720. (See inside back cover for Guide for Submitting Manuscripts.)

Communications concerning books for review and books submitted for announcement in the JOURNAL should be addressed to Allen B. Paul, Economic Research Service, United States Department of Agriculture, Washington, D.C. 20250.

SUBSCRIPTIONS

- Members of the American Agricultural Economics Association receive the JOURNAL as part of their membership.
- Yearly subscriptions, $10. Price this issue $2.50.
- Subscriptions, orders for individual copies of the JOURNAL and changes of address of subscribers should be addressed to C. Del Mar Kearl, Department of Agricultural Economics, Cornell University, Ithaca, New York 14850.

- The AMERICAN JOURNAL OF AGRICULTURAL ECONOMICS is issued five times a year, in February, May, August, November, and December. Prior to 1968, this JOURNAL was the JOURNAL OF FARM ECONOMICS.
- Published by the American Agricultural Economics Association.
- Printed by the George Banta Company, Inc., Menasha, Wisconsin, U.S.A.
- Second-class postage paid at Menasha, Wisconsin.

Population Growth and Agricultural Employment in Latin America, with Some U.S. Comparisons*

WILLIAM C. THIESENHUSEN

Policy makers usually assume that the industrial sector will expeditiously absorb the growth of the labor force. But urbanization in Latin America is so far ahead of industrialization that continued advocacy of the type of agricultural modernization that encourages speedy off-farm migration may merely add to urban unrest. The hacienda system seems to be near the root of the problem and it has an institutional parallel in the sharecropper South of the United States. The campesino and the cropper are, in some sense, analogous; and evidence is presented to show that latifundia-type farming systems are not as able as family farms to (1) provide security of employment or adequate income necessary to keep workers in farming until a late enough stage of development, and (2) support an educational system that is capable of developing the skills needed for urban employment or for upgrading the rural labor force. The seriousness of the current movement to the cities in Latin America is accentuated since slums—the outward manifestation of underemployment and idleness—are growing faster than ours ever did. An agrarian reform policy of "contrived dualism" is briefly outlined; it may be the most inexpensive way to provide employment and increase effective demand, thus "buying time" for the industrial sector to catch up.

BENJAMIN HIGGINS once summarized the major problem of underdevelopment in three words: "too many peasants" [14, p. 120]. Many social scientists agree and believe the problem can be solved only by a massive rural-to-urban transfer of labor.

Formulating the issue in this manner suggests a familiar sequence of prescriptions: (1) push investment in industry to attract farm people to city jobs; (2) substitute mechanization for displaced workers in agriculture to improve labor productivity; (3) improve production per land unit. While this statement of basic strategy is oversimplified, its gross outline has been followed—often unconsciously, sometimes with planning—in many currently developed countries.

Without disputing the necessity of industrialization and the inevitablity of internal migration, we shall argue that in at least some parts of Latin America stopgap policies should be designed to create more jobs for campesinos in farming. This employment should provide greater security and higher income earning potential than farm workers now realize as hired

hands on large estates. The agrarian reform proposal to be suggested should also give these farm people in situ an opportunity to develop some basic skills needed to raise their productivity in agriculture—or for urban life—while providing some demand stimulus to the nonfarm sectors.

Higgins echoes many contemporary social scientists as he argues against a "more-farm-jobs" development program: ". . . the solution may not be to retard the movement to the cities by making conditions more attractive in the countryside—a policy which is in itself anti-developmental—but rather to accelerate the rate of industrialization and consequently the rate of employment creation outside the agricultural sector" [14, p. 136]. But this point of view leaves several questions unanswered: Who will supply the effective demand to provide impetus for industry, considering that 60 to 80 percent of the Latin American farm population has a yearly cash family income of less than $500 [7, p. 6]?[1] Where will the relatively large amounts of capital come from to create needed jobs in industry and to invest in related social and economic infrastructure? How will industry employ the huge work force that will enter the labor market in the seventies, considering that it has not even been able effectively to absorb smaller increases in the past? What will be the socioeconomic consequences of more unemployment and underemployment in Latin American cities where many thousands are now without productive work?

Employment, Population Growth, and the Latin American City

Slightly over half of the population of Latin America now lives in rural areas and slightly under half of the work force is employed in agriculture [41, Table 1–13, p. 63 and Table IV–16, p. 37]. The rate of over-all population growth between 1950–52 to 1963–65 was 2.8 percent per year [41, Table IV–16, p. 37]. The population growth rate for cities in this period was a phenomenal 4.6 percent, representing a rise from the 3.8 percent rate that prevailed between 1940 and 1950 [41, Add. 3, p. 36]. Between 1925 and 1960 the urban work force tripled, while the economically active farm population increased by 50 percent [42, p. 36].

---

[1] Alexander comments on the need for effective demand when import-substituting manufacturing is a primary focus of development policy, as it has been of late in Latin America: "Sooner or later the import-substitution strategy reaches a point of exhaustion. A point is reached at which an economy has installed virtually all those kinds of industries which can produce commodities formerly imported. At this juncture, the nature of the development problem changes. Instead of being the largely physical one of mounting industries for which there is already a market, it becomes one of amplifying existing markets—if the process of development and growth is to continue. . . . [There] are a few Latin American countries—notably Brazil, Chile, Mexico, and Argentina, as well perhaps as Venezuela, Colombia, and Peru—which have completely or nearly exhausted import-substitution possibilities, at least as a major impetus to further development" [1, pp. 305 and 307].

Growth of the urban labor force is caused by the "population explosion" coupled with massive internal migration. Still, off-farm migration has not been sufficient to offset natural increase. To stabilize the agricultural population, the initial annual rate of population growth in the nonfarm sector would have to be about 5.6 percent, approximately one percentage point higher than at present.[2] To reduce farm population in Latin America would require increasing the rate of farm-to-city migration above this figure or reducing the birth rate.

But even at the present rate, internal migration has strained the facilities of the Latin American city. Approximately 5 million families now live in urban shantytowns and slums. This "marginal" population is estimated to be growing at about 15 percent per year—a rate over 10 percentage points higher than the city population as a whole [7, p. 4].[3] And whether the birth rate will slow down in the immediate future in Latin America is an open question. T. Lynn Smith shows that population growth in Latin America between 1950 and 1960 was unprecedented; he believes that there will be some over-all reduction of this rate in the sixties [32]. This contention seems to be borne out by estimates of birth and death rates for a more recent period than the one he examined. Comparing Smith's birth and death rate calculations for 1959–61 with those of the United Nations for 1962–65, one discovers that the crude birth rate in nearly half of the Latin American countries is dropping somewhat faster than the crude death rate.[4] Thus, for the 15 countries Smith analyzed, one finds a drop of between .3 and .6 of a percentage point in natural increase in five countries; a drop of .1 of a percentage point in five countries; a constant rate in three countries; and a rise of between .1 and .2 of a percentage point in two countries.[5]

These data, coupled with Bogue's forecast that "it is probable that by the year 2000 each of the major world regions will have a population growth that is either zero or is easily within the capacity of its expanding economy to support" [5, p. 11], provide some grounds for cautious optimism about the ability of Latin America to cope with its population explosion. But we must remember the speculative quality of these assertions in view of the provisional nature of intercensal data.

---

[2] If agricultural population were to remain stable, nonagricultural population would have to increase at a rate equal to the rate of population growth multiplied by the quotient that results when total population is divided by nonagricultural population. This rate would, of course, be variable over time [8].

[3] Both Manaster [21, p. 25], and Mangin [22, p. 21] estimate the number of urban squatters alone at 25 percent of the population of Lima in 1966. In Rio de Janeiro the comparable *favela* percentage is about 16 [26, p. 50]. Similar percentages could be cited for most Latin American cities.

[4] Compare [32, Table III, p. 21] with [43].

[5] Computed from Ibid.

Moreover, it is sobering to consider that a rapid and immediate decline in the birth rate would have little impact on the size of the labor force for 15 years. Myrdal has further suggested, "Especially since any decrease in the birth rate in an underdeveloped country will ordinarily be a slow and gradual process, we can safely predict that, till the end of the present century and perhaps longer, the labor force . . . in the Latin American countries [will increase] by around three percent . . ." [27, pp. 894–95].

Supplying more jobs in Latin America will be a formidable task. The economically active population in Latin America more than doubled between 1925 and 1960, a 35-year period in which the average rate of population growth was much slower than presently. An increase in the labor force on a similar scale in the United States took the 60 years of high average annual economic growth between 1900 and 1960 [42, p. 35].

Thus, whether Latin American economic policy in the foreseeable future succeeds or fails will depend both on increasing average per capita income and on the related (but sometimes quite distinct) matter of creating adequate employment.

Slow Absorption of Workers in Industry

Economists intuitively look to industry and, more particularly, manufacturing as the major job source in the course of economic growth. But it appears that more employment will be needed than Latin America's secondary sector can possibly provide in the short run. Even its manufacturing component has employed labor at a lethargic pace. Myrdal explains the slow absorption of labor early in the contemporary development process by noting that where manufacturing implies rationalization of earlier and more labor-intensive firms, the new factories ". . . will out-compete craft and traditional production and the net effect on labor demand will be negative . . ." [27, p. 895].

This is an overstatement—but not a gross one—of the recent Latin American situation. In 1950, 7.4 percent of the labor force worked in artisan crafts; by 1965 the figure had dropped to 6.3 percent. This slump more than canceled the slight percentage increase in factory employment, so that the manufacturing sector as a whole (factory work plus artisan industries) employed about 14 percent of the work force in 1950 and only 13.7 percent in 1965. Numbers engaged in manufacturing increased at an annual rate of 2.4 percent from 1950 to 1965, but the rate slowed to 2.1 percent at the end of the period (1960–65) [47, pp. 28 and 29; 41, Table 1-13, p. 63].

The participation of manufacturing in nonagricultural employment sharply illustrates the failure of this sector to utilize the labor force moving into urban centers. Between 1925 and 1960, manufacturing was able to absorb only a little over 5 million of the 23 million added to the urban labor force [42, p. 35]. Put differently, an estimated 35.4 percent of a relatively small nonagricultural labor force were engaged in manufacturing in 1925; but by 1960, as urbanization advanced, the percentage had dropped to 27.1 [47, p. 26]. In most developed countries, the ratio of manufacturing jobs to urban employment remained essentially constant over long periods of time—and at a much higher level.[6]

In sum, a 5.6 percent average annual increase in manufacturing output was associated with a 2.1 percent average annual growth in employment between 1960 and 1965.[7] While it is hoped that investment and effective demand can remain high enough to increase both rates, the output-to-labor ratio will probably become more unfavorable to employment in the future. From a technological standpoint, manufacturing in Latin America is likely to become less rather than more labor intensive. It may be possible to foster economically justifiable policies that retard this trend in a few industries from time to time, but it is difficult to see how enough jobs can be created thereby. For example, income redistribution policies should shift the demand structure for manufactures (in the short run) away from its current emphasis on intermediate and even heavy lines to more labor intensive consumer nondurables, for which markets are presently exhausted in most Latin American countries. This development would also ease balance of payments difficulties. Even so, Barraclough explains, "A new factory in Medellín or São Paulo will generally adopt the labor saving technology of industries in present-day Detroit or Pittsburgh, not that of 19th century Birmingham or Manchester" [2, p. 19].[8]

The picture is not much brighter in the industrial sector as a whole

---

[6] Experience in industralized nations points to two basic features: (1) a relatively high percentage of urban employment is engaged in manufacturing, and (2) this percentage persists over long periods. "Thus, for example, it has been shown that the percentage in the United Kingdom in 1951 (51.9 percent) was practically the same as in 1901 (51.1 percent); in Italy, after a slight decline during the twenties, the percentage remained little below that for the beginning of the century (59.5 percent in 1901; 56.6 percent in 1939; and 53.5 percent in 1954). . . . In the United States the percentage has been lower, but has also shown very little tendency to decline over the long term (47 percent in 1870; 44 percent in 1900; 45.4 percent in 1920; and 42.3 percent in 1950)" [42, p. 36].

[7] Computed from [41, Tables 1–11 and 1–13, pp. 50 and 63].

[8] Glade [11] argues that in the initial push toward import substitution in the '40's and '50's, manufacturing activity was concentrated in nondurable consumer goods many of which were, relatively speaking, quite labor intensive. By the mid-fifties, however, major dynamism had gone out of these fields, and the focus of industrialization shifted to consumer durables and basic industrial goods that are less labor intensive. Miller [24] shows that employment stabilization policies and, by inference, some other kinds of social legislation have contributed to a decline in employment opportunities and increasing substitution of capital for labor in the secondary sector. See also [42].

(mining, manufacturing, construction, and associated technological services). In 1950–55, it employed 44 percent of the addition to the nonfarm labor force; in 1955–62, only 36 percent [39, p. 40].

Because the nonfarm goods-producing sectors have not absorbed a substantially larger percentage of a growing labor force lately, more workers are drifting to the tertiary sector ("other services") and to what the United Nations has called "unspecified activities"—mainly disguised unemployment. In absolute numbers, 1965 employment in these subsectors was nearly double that for 1950—a growth that does not seem to be in line with the need for services engendered by the region's slow rate of economic growth [47, p. 29; 40, p. 62 and Table 1–13, p. 63].

The Economic Commission for Latin America recently elaborated on the oversimplified assumption that "other services" and "unspecified activities" provide the only refuge for the nonfarm underemployed by observing that all sectors seem to have high-, medium-, and low-productivity subsectors. It estimates, for example, that in manufactures, construction, and technological services, the work force allocated to each productivity subsector would be about 20, 60, and 20 percent, respectively. As urbanization proceeds at a rate faster than industrialization, new in-migrants—if they are absorbed at all—are employed in the low-productivity subsector [47, pp. 30–31]. It stands to reason that if the economies of Latin America do not grow much faster and if rural-to-urban migration continues at the present pace, the capacity of this subsector to provide jobs will become saturated, raising open unemployment to very high levels [44; 47, pp. 32–35].

One can conclude, therefore, that industrialization must be given as much impetus as scarce resources allow, but that unless Latin America is willing to suffer the massive social unrest that idleness and underemployment may well spark, agriculture must be relied upon not to repel workers to the extent it has in the past. This is not because of any inherent advantages of farm employment, but because the capacity of industry to utilize labor in Latin America is not as rapid as necessitated by the high rate of in-migration.

Farm Financed Social Welfare: the U.S. North, the South, and Latin America

Even though there are indications that much privately owned farm land is not used to capacity, given present technology [16], agriculture in most of Latin America does not now provide an adequate haven for underemployed and jobless people. One reason is to be found in the manner in which farming is organized. Large estates (plantations or haciendas) encompass most of the best land—except in Mexico, Bolivia, and Cuba—

and are worked by large numbers of hired laborers who have little or no bargaining power.

When farming is structured in this manner, it: (1) does not provide either the security of employment or adequate income necessary to keep workers in farming until a late enough stage of development and (2) does not permit a viable community organization to flourish that would support an educational system capable of developing basic literacy and the skills and attitudes needed for urban employment or for upgrading the rural labor force.

When management is separated from the more-than-ample supplies of poorly-organized labor, as in the estate system in Latin America, resource owners can offer an extremely low wage and are freer than in a family farm system to discharge workers who have few employment alternatives.

On the other hand, while an owner-operator may sell out when the situation becomes acute, he cannot fire himself or his family labor when he is caught in a cyclical cost-price squeeze. Consequently, in a system dominated by the family farm a large proportion of surplus labor takes the form of involuntary underemployment in the countryside rather than involuntary unemployment in town. Even today U.S. agriculture harbors a surprisingly large amount of surplus labor.

As Owen has argued, farming in the United States has thus performed a self-financed social welfare function: redundant labor resources have not only funded their own sustenance, they have also been expected to cover a substantial percentage of their schooling costs and to support a large portion of other necessary social overhead capital [29, p. 62].

With each passing year, U.S. agriculture performs this function less adequately. By relying too heavily on farm-financed social welfare, our affluent country has consistently overlooked its rural poor [30]. While liberals may abhor this neglect, they must admit that the "agrarian dualism" which developed throughout this century had some important advantages: one subsector of farming has provided immense production, while the other afforded a stopgap matrix of jobs that retarded premature cityward migration. Through primarily locally financed schools, agricultural communities have helped to prepare farm people to be more productive in agriculture if they remained, and in urban employment if they migrated.

U.S. agricultural dualism has not been static; land in the welfare subsector constantly "moves" into the growth subsector in response to the dynamic functioning of the market. Labor-saving capital has now become so cheap relative to labor that for the past several decades farming has been caught in an accelerated combination of farm units accompanied by a release of labor. Labor has not always benefited from these land and capital "flows." That some entire communities have been "left behind" is but one indication that farm-financed social welfare has not worked altogether smoothly; this implies that supplementary policies to cope with rural poverty in the United States are long overdue.

But in some parts of our country—notably much of the South—farm-financed social welfare never was a part of the institutional framework. To the degree that the southern sharecropping system separated ownership-management from labor (that had little countervailing power) and discouraged the education of the farm work force, it can, albeit roughly, be compared to the Latin American hacienda or plantation. Indeed, the southern cropper may be considered as one U.S. analogue of the Latin American hacienda worker.[9]

These farming systems seem to have serious urban repercussions. In the United States, the problems of today's ghetto are not due to racial prejudice alone (in boom periods, Negro unemployment in cities does drop somewhat). They are at least partly due to the release of an unskilled and even illiterate labor force that could not be fully hired by industry at the stage of development it was passing through. Kain and Persky conclude:

> The North's biggest cities attract large numbers of rural Negroes from the Core South. Smaller Northern areas draw disproportionately large numbers of Appalachian whites. Ironically, it is these groups that are relatively the worst prepared for coping with the complexities of the industrial, metropolitan North. The educational achievement of each is inferior to the majority of the Southern population from which they came. Negroes of the Core South are especially disadvantaged in this respect. In analyzing the distribution of poverty in the North Central region of the country, we found that a substantial fraction of the metropolitan North's poor were born and educated in the South. . . . Finally, we have found no evidence to support the widely held view that rural Southern migration to the North will soon abate [17, pp. 73–74].

And if the central city problem here has some roots in a remnant plantation system, which represents only a small fraction of U.S. agriculture, one cannot but be alarmed at the potential for social unrest in most Latin American countries where the preponderance of the land is organized along similar lines and where slum settlements are growing faster than ours ever did.

As the campesino was deprived of land from colonial times, so was his U.S. counterpart—especially if he was black. Even the Homestead Act benefited the black little; his pleas for "40 acres and a mule" after the

---

[9] There are other analogues, like the "company town" poor white from Appalachia and the blacks of the central cities who live in absentee-owned slum units and may be victimized by high rents as well as lack of community control.

Civil War largely went unheeded [23].[10] Recent commentators have noted of the immediate *post bellum* period: "The planters still owned the land but they needed a labor supply to farm it. As a result, a new kind of partnership—sharecropping—was formed. The landowners supplied land and work stock and the newly freed Negroes supplied the labor to continue farm production in much the same pattern as before . . ." [20, p. 11].

Movement of blacks out of the South was slow in the late nineteenth century because of adequate employment possibilities in agriculture and a great deal of competition for northern industrial jobs by recent immigrants—mainly of European stock. But during the early 1920's, "The enormous growth of northern industry, the increasing demand for unskilled labor, and the relatively high wages offered by business enterprise, and above all the curtailment of European and Asiatic immigration multiplied the opportunities available . . ." [4, p. 26]. Subsequently, World War II created unprecedented demand for labor and encouraged a much larger out-migration of farm workers. Now, higher welfare payments in the North than in the South seem to provide an additional attraction.

But out-migration also had its "push" aspects—employment possibilities on large cotton farms began to decline in the '20's: "For a few years the boll weevil caused great panic as millions of acres of cotton were severely damaged and production fell . . . thousands of Negroes emigrated as the landlords turned to livestock and dairying" [3, p. 164]. Soil depletion and erosion were the other major problems, especially in the Piedmont country of Georgia and South Carolina, and impelled thousands to leave. The depression, when "the bottom dropped out of the cotton market," seems to have had similar effects [3, p. 164]. In later decades mechanized planting and subsequently mechanized harvesting of cotton discharged more southern workers at a time when the labor market was unable to absorb them in sufficient numbers [6]. And in the sixties, as yet uncounted numbers have been pushed off the farm by reductions in cotton allotments [45, p. 52], and by employers' response to the 1966 extension of the minimum farm wage legislation [30, p. 22].

Had the sharecrop system supported adequate schooling, more blacks doubtless would have gotten urban jobs despite the scourge of discrimination. But at the same time that former sharecroppers were being released from southern farms in ever larger numbers, the ratio of skilled-to-unskilled labor required by industry began to rise in accelerated fashion.[11]

---

[10] Any description of the plantation-sharecropping system sounds strikingly like that of a hacienda in, say, Peru or Chile. See, for example, [31] and compare this description to one of a latifundia in [16].

[11] The latter day manifestation of this is particularly serious to the U.S. economy. "In [the] word 'skill' lies the answer to the seeming paradox of 3,000,000 unemployed

Describing the inadequacy of the rural southern educational system to prepare workers for these jobs, one commentator [3, p. 188] has noted:

> In 1960, the average years of schooling completed by the nonwhite farm population 25 years old and over was 5.7 years, compared with 8.9 years for the white farm population and 11.1 years for the total urban population.

This says nothing of the comparable quality of schools educating blacks and whites. Nicholls places blame for this situation squarely on the planters:

> In striking contrast to most of the Middle West, the South has been dominated by power groups who, shunning the public schools in the education of their own children, see little reason to tax themselves in order to finance the education of the less privileged classes . . . [28, pp. 110–11 and 113].

Poor farmers who remain today in the planter-dominated parts of the rural South are often nearly destitute and are permitted to remain—in houses they do not own, on land which is not theirs—only because of the paternalistic spirit of large holders. And a high percentage of those who migrated are today living in the ghetto where unemployment—or subemployment—is high.[12] If jobs in the industrial era of our history have become progressively more scarce for the unskilled, one cannot but be alarmed at what this implies for the dawning technotronic age.

Several Tentative Hypotheses

While retrospective conjecture may result in highly inaccurate representations of history, we may pose several plausible but tentative and overlapping hypotheses from our experience with direct relevance for contemporary Latin America: Had a land tenure system that was labor absorptive over the long run been established in the rural South after the Civil War, recent out-migration would not have been as rapid. When it occurred it would have represented a more genuine response to viable economic opportunities. And if that tenure system had fostered farm-fi-

---

and a concurrent shortage in manpower. The unemployed are chiefly those who are, in various ways, unskilled. It is our national shame that a very large part of the unemployed are Negroes in slum ghettos who have neither the education nor the training in a specific skill to get a job . . ." [35, p. 8].

[12] In early 1968, unemployment was as low as it has been in the past decade and a half, 3.5 percent of the labor force. But this rate was twice as high among Negroes and higher still among young Negroes living in the nation's slums. In addition to those who are looking for work and cannot find it—the unemployed—the slums hold those who do not have jobs and are not looking for them and those who are looking for full-time jobs and can find only part-time jobs. When all of these groups are combined, the "subemployment rate" reached 24.2 percent in Boston's Roxbury; 28.6 percent in Harlem; and 34.2 percent in Philadelphia, for example [19].

nanced social welfare, laborers would have reached the urban labor market more adequately prepared for urban life.

Evidence bearing on this speculation is scanty. But when all rented and sharecropped units in the South—as well as those that are partially or fully owned—are counted as farms, in all but four census periods from 1900 to 1964 either (1) numbers of farms operated by blacks disappeared more rapidly than farms operated by whites, or (2) numbers of Negro units declined while numbers of white units increased (Table 1). Differences in the opposite direction in the four exceptional periods were slight. Thus, it appears that through most of this century the institutional framework of Negro agriculture has been less able than the white system to hold labor and that this situation becomes steadily more unfavorable to the black as the century wears on.

Table 1. Percent increase or decrease in number of farms: the U. S. South[a]

Census period	Percent increase or decrease of nonwhite farms[b]	Percent increase or decrease of white farms	Percentage points of difference
1900–10	20.2	17.4	+ 2.8
1910–20	3.7	3.5	+ 0.2
1920–25	− 9.9	0.7	−10.6
1925–30	6.0	1.8	+ 4.2
1930–35	− 7.5	11.3	−18.8
1935–40	−16.6	−10.7	− 6.1
1940–45	− 2.2	− 4.8	+ 2.6
1945–50	−16.0	− 5.5	−10.5
1950–54	−17.1	−11.4	− 5.7
1954–59	−42.7	−25.6	−17.1
1959–64	−32.0	−13.5	−18.5

[a] Alabama, Arkansas, Florida, Georgia, Kentucky, Louisiana, Mississippi, North Carolina, Oklahoma, South Carolina, Tennessee, Texas, and Virginia.

[b] Farms include the full array of tenure types from full ownership to cropper, including all rented land; the "nonwhite" census designation approximately equals "black" in the South.

Source: *1959 Census of Agriculture,* Vol. II, General Report: Statistics by Subject, Table 5, pp. 1032–33. 1959–64 data calculated from *1964 Census of Agriculture,* Vol. II, General Report, Ch. 8, Table 3, p. 756.

Looking only at farm consolidation one may, on balance, understate the amount of Negro off-farm migration that occurred. Since rural blacks have families that are larger than the families of rural whites, there are proportionally more people who must leave for other work at some time in their life cycle—even when the family head is not fired. Each 1,000 nonwhite farm women 40–44 years old in 1960 had given birth to an average of 5,618 children; each 1,000 rural white women in this age bracket had borne an average of 2,873 children [45, pp. 52–53].

The issue becomes somewhat clearer when race is distinguished from tenure type. Table 2 omits all tenants but croppers, the tenure type most intimately associated with the remnant plantation system. In each census period after 1925–30, farm owners in the South (the majority, of course, family farmers) have been far more able than the croppers—whether white or black—to remain in agriculture. Some croppers became hired farm labor in mid-century, but on the average only one hired hand was engaged for each three or four croppers that were discharged [45, p. 51]. It should be noted that there is more similarity in the trends within the "owner" and the "cropper" categories than within those of "white" and "black." Thus, the plantation sharecrop "system" seems to have contributed importantly to reducing the job opportunities in agriculture; it seems less able than family farming to maintain employment in the face of adverse prices (the '30's) or mechanization (the '40's and '50's).

Table 2. Percent increase or decrease in number of owned and cropper farms: The U. S. South.

Census period	Farm owner		Cropper	
	Percent increase or decrease of nonwhite farms	Percent increase or decrease of white farms	Percent increase or decrease of nonwhite farms	Percent increase or decrease of white farms
1910–20	1.9	6.3		
1920–25	−10.6	− 4.4	3.2	11.0
1925–30	−12.0	−10.5	14.1	24.6

Race is a lesser complication in much of Latin America, but the hacienda system seems no more viable than the sharecrop system in providing adequate educational facilities or a stopgap matrix of jobs.

Absorption of Labor in Agriculture in Latin America

Like the remnant southern plantation, the hacienda is not noted for its ability to absorb labor. The set of studies by the Inter-American Committee on Agricultural Development [16; summarized in 41, Add. 4], which focuses on seven Latin American countries with a traditional agrarian structure, shows that production per acre is inversely related to farm size; and while latifundios are 400 times larger than *minifundios* on the average, they employ only 15 times more workers.

As in the U.S. South, a variant of noblesse oblige has been some substitute for self-financed rural welfare on family farms—owners who feel responsibility for their workers' protection have not fired resident labor even after the factor is in surplus [28]. But in Latin America, as in southern United States, this spirit is no longer widespread.

More serious than the issue of resident labor, proportionally fewer seasonally hired workers (who make up the bulk of the rural labor force) are now being contracted. A noticeable shift in some countries is being made from cash crops—which require a substantial amount of labor—to livestock. Then, too, pressures for the adoption of labor-saving farm technology in Latin America are similar, if not yet as pervasive, as those in industry. Minimum agricultural wage legislation is making labor more expensive in relation to capital. In some countries, notably Venezuela, those who mechanize are often able to obtain machinery at relatively low cost with cheap credit and long term repayment arrangements. While sometimes necessary to increase product per unit of land, the effect of mechanization on production—which is primarily labor displacing—is usually not as great as would be equivalent expenditures on yield-increasing inputs such as fertilizers, hybrid seeds, and protective chemicals.

Even if land taxes that cannot be evaded are utilized as a means to modernize agriculture, large landowners may find it profitable—at least as long as inflation continues—to dislodge workers and substitute capital for labor to meet this new fixed cost, instead of selling out.

Education of the Rural Labor Force in Latin America

Landlords who dominate Latin American economies and politics usually send their children to urban schools. Hence, those with investable funds have little interest in improving rural education. In Chile, generally considered to have one of the most progressive school systems in Latin America, only four of ten urban first graders ever advance through the sixth and final elementary grade; of every ten rural students who enter primary school, only one is graduated. The dropout rate is higher in the countryside than in town because of longer distances to school, more illness, greater labor needs at home, poorer facilities, and fewer books. Most dropouts leave before they learn to read and write [46; 47, pp. 43–48].

Primary school graduates are only slightly better off. The curriculum in the grades is largely unrelated to the background of the students or to the occupational role they might play if they migrated to town. Furthermore, teachers are usually poorly prepared. For example, in Brazil there are 90,000 employed teachers who have not finished their primary education [12, p. 15]. In Colombia, 41 percent of the urban primary teachers, but 78 percent of the rural, have no more than a primary education [13]. Needless to say, if the products of this system migrate to town, they are ill-equipped to even take unskilled jobs.

By contrast, in Mexico, where the hacienda system has been abolished, one observer [18, p. 52] recently noted:

> There is an upsurge in the literacy level among the young and there are some signs of improvement among the older generation as well. . . . It is not easy to estimate how far the investment in human resources will go, but the course has been charted and the vision of the future quoted below [by Frank Tannenbaum in 1950 from a conversation with President Calles] may not prove to be an idle dream: "in the past Mexico was divided into *latifundios,* with a big house (*casco*) in the center; in the future we will organize it around the village, with a school in the center."

Citing the experience in Bolivia since haciendas were broken up as part of the revolution of 1952, Hobsbawm states, "The first thing any peasant community does when it can is to build a school" [15, pp. 54–45]. In 1964, Mexico allocated nearly a quarter of her annual budget to education, a figure exceeded only by Costa Rica among the 19 Latin American republics. Bolivia spent 17.9 percent of her budget in education; only the aforementioned and El Salvador, Panama, and Honduras had better records [40, p. 39].

Implications for Agricultural Development Policy in Latin America

Unless other policies intervene, one impact of agricultural "modernization" now occurring in most of Latin America may be that workers will leave the farms for cities at an increasing rate in the next decade. This argument implies that a concerted effort should be made to slow the rate of farm-to-city migration until industry is able to absorb labor at a faster rate. Unfortunately, colonization of new lands in Latin America may be too slow and expensive and some measure of land reform may be the only alternative for the task at hand, in spite of the understandable opposition of the landed.[13]

To partially meet immediate employment needs, "contrived dualism," which has parallels in the historic development of agriculture in our North and West, might be considered by development planners in Latin American countries with a traditional land tenure structure:[14]

(a) *Subsector that emphasizes growth in marketable surplus.* It would seem as though the progressively managed large farm and plantation subsector should be stimulated to greater productivity through the application of more yield increasing inputs, since these are the farms that feed the city and provide export earnings. At the same time, as much employment and income security as possible should be encouraged in this subsector without creating disincentives for management.

---

[13] Especially since the writings of Ragnar Nurkse, the possibility of a capitalistic system providing the rural underemployed with productive work through rural public works projects has been recognized. See a late advocacy of this position in [25, pp. 64–66]. The present author does not argue with the desirability of this policy alternative but doubts that it is sufficient for the task at hand.

[14] The following points are detailed in [36] and [37].

(b) *Subsector that emphasizes growth in employment.* The existing subsector of very small farms can probably continue to absorb some population increase until development-created employment begins to catch up with population growth. If technology can be adapted to their needs (as in Japan and Taiwan) and if markets and credit can be made available to them, these small farms might employ even more people and make a greater contribution than presently to marketable surplus.

Programs to provide secure and legal title for present occupants may be inexpensive and are of great importance in some areas. Most Latin American countries have farmers who are "squatters" on public lands; there are several hundred thousand farmers who do not have title to the land they farm [38]. This is not conducive to employment stability, nor does it offer the security required for long-term investments in agriculture.

Since underutilized and poorly managed land on traditional large-scale farms contributes little to production, and since its absentee ownership and paternalistic labor patterns are vulnerable to labor unrest and consequent worker eviction, it should be transformed into new peasant farms. Past performance gives no indication that large investments in the traditional subsector of agriculture would result in either enough increased production or rural employment to meet the needs of the growing population.

As with existing small farms, attempts should be made to move reform-created farms as rapidly as possible toward commercial agriculture with limited mechanization, more use of yield-increasing inputs, and improved extension-type services. Given the exceedingly scarce supply of resources available, however, this may need to be regarded as a long-term goal rather than a present possibility. Even if, for the time being, reform does no more than provide sustenance for large numbers of rural people, it will contribute to economic and political stability and buy time for industrial development to catch up with population growth. As the labor market tightens, land and capital should be freed for the "primarily marketable surplus" subsector. That this will happen only over the long run because of the current high rate of population growth should not surprise us.

A high cost colonization program will be counterproductive; if it costs more to settle farmers on the land than to secure a job in manufacturing (as unfortunately it has in some countries), land reform will soon grind to a halt. If "agrarian reform" actually displaces labor—as it also may have done in some countries—it will not have fulfilled its prime objective [34]. Whatever program is adopted, settlement cost per family must be low.

Furthermore, the need is for flexible agrarian policies and more research on an exceedingly complex situation. Doctrinaire and ideological solutions are inappropriate, not only because conditions vary from country to country, but also because the policy needs of a given country vary over time. Thus, the post-reform tenure system may or may not take the form of the family farm.[15] In general, however, the emphasis should be on increasing production at low cost through yield-increasing technology along with maximum employment and employment security. A cue—but no recipe—can be taken from U.S. history, and emphasis should be placed on creating a milieu in which farm-financed social welfare can become part of the institutional fabric.

If the current population growth rate continues for several decades, no stopgap expedient of agricultural employment will be able to provide enough jobs to accommodate the burgeoning work force.[16] And only a completely unprecedented rate of economic growth will be able to provision it.

Even if the birth rate should fall in the seventies or eighties, if little or no land reform takes place in the meantime, it is likely that by the nineties or even sooner social scientists will be studying ways to reconstruct after a complete institutional breakdown in Latin American cities.

[15] Even though a type of cooperative farming known as the *asentamiento* is being utilized in the early stages of the current Chilean reform, research on eight such farms the year after incorporation into the program [10] shows that both employment and production practically doubled from the pre-reform situation. Whether this type of organization is too expensive relative to output, whether it will be viable over the long run, whether it is adversely influencing the existing commercial subsector of agriculture, and even whether it can survive the serious 1968 drought are matters for further research and observations. Over time, it is conceivable the asentamiento may have the problems that have plagued the proportional profit farm in Puerto Rico. Relieving unemployment had been one avowed intent of this land tenure arrangement. Now, 16 unions bargain with the Land Authority, the government agency vested with most management functions. They have pursued a militant wage policy, coupled with featherbedding techniques that have increased operating expenses and caused consistent negative profits on some farms [9, 33].

[16] Absorbing labor until industry was ready to provide employment was one avowed goal of the Mexican reform. Even though the Mexican industrial sector is now the most dynamic in Latin America, population growth continues high. Numbers of landless workers are increasing rapidly and there is little more land available to accommodate them. In this context, one cannot fall back on the agricultural sector for additional stopgap employment. Continued high rates of population growth, it seems, will eventually thwart all possibilities of providing the work force with jobs.

Determinants of Farm Family Income Inequality*

BRUCE L. GARDNER

Income inequality is classified as "long run" when due to the distribution of resource ownership and "short run" when due to transitory disturbances or variations in returns to comparable resources. Owing to deficiencies of census size distributions of income, data pertaining to the distribution of human and non-human resources are used to estimate long-run inequality for each state. A cross-sectional regression analysis of state differences in inequality and changes from 1949 to 1959 yields the following results: (1) labor market adjustments have been influential in reducing short-run but not necessarily long-run inequality; and (2) increases in the capital-labor ratio, the average level of schooling, and research and extension are all associated with increasing dispersion of farm incomes, though also with increasing average incomes of farmers.

THE AIM of this paper is to gain some understanding of the process that determines the inequality of the personal distribution of income among farm people—especially with respect to the consequences of technical progress, off-farm migration, and related developments in U.S. agriculture. Although these events have received considerable attention from economists, little is known about their influence upon the distribution of income within agriculture.

The plan of the paper is, first, to develop an analytical framework for the investigation of income inequality; then, to treat the problem of appropriate procedures for measuring income inequality; and finally, to present estimates of cross-sectional regressions (by states in 1949 and 1959) of measured income inequality on variables intended to represent important developments in U.S. agriculture.

A Framework for the Analysis of Inequality

At least since the time of Ricardo, economists have sought a general explanation of the distribution of personal income. The most useful development in this area has been the work that culminated in the marginal productivity theory of the functional distribution of income. But the link between the functional and personal distributions of income is incomplete in that the marginal productivity theory provides no explanation of the inequality of factor ownership; and although many alternative hypotheses

---

* This paper is based on the author's Ph.D. thesis [7]. He wishes to thank T. W. Schultz, D. G. Johnson, George Tolley, Margaret G. Reid, and Zvi Griliches for advice and criticism at various stages of the investigation.

BRUCE L. GARDNER *is assistant professor of economics at the North Carolina State University.*

have been put forth, there exists no comprehensive theory of income inequality on which to base this investigation.

A problem in this literature is that various and sometimes conflicting views exist on just what kind of process generates the distribution of personal income. Champernowne, for instance, advocates a view that the size distribution of income is generated by a stochastic process [5]. Meade [13] emphasizes the role of savings behavior and patterns of inheritance in determining the long run distribution of income and wealth. Becker [3] developed a theory of the personal distribution of income based on investments in human capital. There are also such specialized hypotheses as Pareto's contention that there tends to exist in any capitalist society a natural, constant degree of inequality [14, p. 648], and Friedman's analysis of the size distribution of income on the basis that individuals with different risk preferences will choose investments which have varying degrees of risk [6].

How can such hypotheses be put to use in analyzing farm income inequality? It is useful at this point to distinguish two types of determinants of inequality and two levels of analysis corresponding to them. The first level, the level of "immediate" determinants of income inequality, derives from the accounting identity of an individual's income as the sum of the payments to factors of production owned by him, so that income inequality can be analyzed as a function of the distribution of factors of production and the rates of return to them. Second, there are the "ultimate" determinants—the factors which influence rates of return and the distribution of factor ownership. A framework for the analysis of the immediate determinants is provided by the marginal productivity theory, as developed in the following section. For the analysis of the ultimate determinants, however, it is necessary to resort to hypotheses like those listed above. But these hypotheses have no direct relationship to the ultimate determinants considered in this paper—the recent developments in U.S. agriculture mentioned above. Accordingly, it will be necessary to develop specific theoretical propositions about the consequences of these events.

The Distribution of Personal Income in Equilibrium

The income of a farm family may be expressed as a function of the labor and capital it owns, the rates of return to them, and a transitory component.

$$Y_i = w_i L_i + r_i K_i + \epsilon_i \tag{1}$$

where Y is current income, w is the wage rate, L is labor supplied, r is the rate of return to owned capital, and K is the value of capital owned. The transitory component includes all unanticipated income (which may be negative). It is assumed to have an expected value of zero and to be uncorrelated with the other terms of (1). Anticipated income is of two basic kinds: income received under conditions of long-run equilibrium and receipts (or losses) attributable to disequilibrium–short-run variations in r or w due to lags in adjustment to changing market conditions.[1]

This classificatory scheme is arbitrary in that one could treat unanticipated work accidents, price changes, etc., as creating divergences between actual and equilibrium rates of return rather than as separate items (ε). The merit of treating unpredictable sources of income variation separately from those that are predictable, but for which long run adjustments are not possible (or do not pay) in the short run, is that the forces influencing the two are not the same. Therefore, the theoretical analysis of income inequality is done more conveniently when these two sources of inequality can be logically (though in this paper not practicably) separated.

The most important distinction to be drawn, however, is that between both types of short-run income variation, on the one hand, and variation that persists in the long run, on the other. Let $w_i = w_e$ and $r_i = r_e$. Then $Y_i - \epsilon_i = Y_E$ is the "equilibrium income" of the ith family. The relative variance of equilibrium income is "long-run income inequality"—inequality that remains when transitory receipts and market disequilibrium are eliminated. The variance of equilibrium income is

$$V(Y_E) = w_e^2 V(L) + r_e^2 V(K) + 2 w_e r_e \, \mathrm{COV}\,(L, K) \tag{2}$$

which, when put in relative terms by dividing by $\bar{Y}^2$ and multiplying by $(\bar{L}/\bar{L})^2$ and $(\bar{K}/\bar{K})^2$, yields

$$C^2(Y_E) = f_L^2 C_L^2 + f_K^2 C_K^2 + 2\rho f_L f_K C_L C_K \tag{3}$$

where V denotes variance, C the coefficient of variation, f the relative shares of L and K in total income, ρ the correlation coefficient between L and K, and bars represent means.

In this context, the possible ways in which the relative variance of equilibrium income can be changed are: (1) shifts in the variance of labor or capital ownership, (2) changes in the relative share of labor or capital, and (3) changes in the covariance between labor and capital ownership. These are the immediate determinants of income inequality. The ultimate determinants will be taken up after dealing with some problems of measuring inequality.

---

[1] A problem here is that a change in labor market conditions, for example, may be anticipated by some individuals but not by others because of differences in ability or in investment in information. Such differences among individuals are essentially a matter of non-homogeneity of L and, hence, cannot be handled in terms of equation (1). This difficulty is treated further below.

The Measurement of Income Inequality

The basic data available pertaining to income inequality are the size distributions of rural farm family income of the U.S. Census of Population [20, Vol. 1, Table 65], given by states for 1949 and 1959. The income of these distributions is *annual money* income. The variance of a census income distribution differs from $V(Y_E)$ in that the census data include the variance of transitory income and variations in rates of return due to disequilibria, precisely the items of short-run income inequality that were left out of $V(Y_E)$. On the other hand, some sources of income are included in equilibrium income but not in the census data, namely, non-money income and capital gains.

Given these differences, will the use of census income distributions impair the explanation of state differences in inequality? Yes; first, because of the omission of capital gains. If a new or improved input is developed, for example, at first there will be unanticipated gains or losses, then perhaps some disequilibrium; but after complete adjustment, the consequences for equilibrium income show up in the value of resources whose long run supply curves are not perfectly elastic. The same sequence applies for a shift in product demand. The most important instance of this effect is probably the capitalization of the benefits of government programs into land values—not only for commodity programs but also for such activities as subsidized or tax-exempt irrigation, etc. The census data do not show the wealth effects of any of these factors.

An even more fundamental problem is created by the inclusion of both short- and long-run sources of inequality in the census data. Migration may increase the relative share of capital in income, as discussed below, thereby increasing long-run inequality. But since labor migration is in a sense just the overcoming of immobility, it should be expected to *reduce* the short-run component of income inequality. Of course, this reduction, if it occurs, is important and will be considered separately in the empirical analysis. The point here is that it is impossible simultaneously to identify the positive effect of migration on long-run inequality and its negative effect on short-run inequality when both are included in the same measure.

An Alternative Measure of Income Variance

For the reasons discussed above, the variance of a census size distribution of income is an unsuitable measure of income inequality for the purposes of this paper.[2] Accordingly, I attempted to construct an alternative measure of the relative variance of income by estimating the right hand side of equation (2) for each state.[3] This procedure provides a direct measure of long-run inequality, leaving out any variance attributable to short-run factors. This section treats the main problems encountered in the attempt to measure the various elements of equation (2). The full details of the data and procedures used are not presented, but are available from the author.

---

[2] The census data also contain serious random and systematic errors due to misreporting, grouping of large discrete income classes, and the absence of class means. However, the data I intend to use as a substitute for the census size distributions create equally as many problems, maybe more. The main reason for my alternative approach is that it gets *conceptually* closer to the variance of equilibrium income.

Labor income

A first crucial problem is that the specification of (2) is unrealistic in assuming that the equilibrium rate of return to each unit of labor and capital is the same. This problem is most serious for the labor variable; the variance of earnings undoubtedly reflects a good deal more than the variance of time spent working. Accordingly, $V(L)$ was expanded to take into account quality differences attributable to natural ability and acquired human capital.

The elaboration of $V(L)$ is based on the use of an income generating function, as in Welch [22]. The income generating function treats a family's earnings as a function of socio-demographic characteristics presumed to determine income. The coefficients of the function show the effect upon income of having a particular set of characteristics, e.g., being over age 65 with zero schooling. The characteristics that the Census of Population data allowed to be considered were the age, schooling, and race of rural farm family heads and the number of earners per family in 1959.[4] Given the coefficients of the income generating function and the joint distribu-

---

[3] The estimated form of (2) was logarithmic, which implies that variances are already in relative terms. The log variance, however, is weighted by factor shares as in (3) rather than rates of return, since the log form of (1) implies that

$$(1') \qquad Y_i = L_i^{\omega_i} \cdot K_i^{\gamma_i} \cdot u_i$$

Given that the marginal contribution of K to Y equals the equilibrium rate of return (r), we get (dropping subscripts):

$$\frac{\partial Y}{\partial K} = \gamma \cdot L^{\omega} K^{\gamma - 1} u = r$$

$$= \frac{\gamma Y}{K} = r, \text{ i.e.,} \qquad \gamma = \frac{rK}{Y}$$

The log form of (2) is thus equivalent to (3) except that log variances replace the coefficients of variation.

[4] For 1949, none of the census cross-classifications of age and schooling with income were available by states. As a result, the 1959 coefficients of the income generating function were used with the 1949 distributions of the characteristics, except for age in the 65 plus group (because of the extension of social security benefits to farmers during the decade). This coefficient was adjusted by using the change in the logarithmic age-income profile between 1949 and 1959. In addition, data were not available on the covariance between labor and capital (the third term of (2)) for 1949.

tion of the characteristics in each state, the variance in income attributable to the variances and covariances of the characteristics can easily be calculated. The result is an estimate not of $V(L)$, but of the whole first term of equation (2); it is an estimate of the variance of equilibrium labor income.

The resulting state estimates of the log variance of labor income had an average value of .28. Since the standard error of the estimated variance (derived from the standard error of the coefficients of the income generating function) is about .04–.05, it is clear that the estimates lack precision. The standard error of the estimated *differences* between states, however, is much smaller because the set of coefficients of the income generating function was the same for each state.[5] Differences between states are introduced only by differences in the distributions of the characteristics.

The income generating function used has the weakness that a family's labor income is taken to be determined by the characteristics of its head plus the number of earners in it. This specification ignores variations in the characteristics of secondary earners. It also leaves out variations in income due to factors not classified in the census; most importantly, differences in natural ability, motivation, and tastes, as well as acquired human capital not captured by years of schooling. As a result, the absolute value of the variance of equilibrium labor income is probably seriously underestimated. However, to the extent that any of the left out factors are correlated with the included characteristics, e.g., schooling, their effect will be picked up by the estimates; and the remaining understatement will not affect the comparisons between states to the extent that the degree of understatement is similar everywhere. The variance of natural ability, for example, may be reasonably constant from state to state.

Income from non-human wealth

The Census of Population contains no data on the ownership of non-human wealth. In fact, for non-farm families, an analysis like the present one could not be done simply because state data on $V(K)$ do not exist. For the agricultural sector, however, the Census of Agriculture contains information on the size distribution of the main agricultural assets within each state.[6]

---

[5] Except that regional variation was allowed for the coefficients of race and the characteristic "zero earners"; also, the schooling coefficients, which were based upon Welch [22, p. 89], varied from state to state.

[6] A size distribution of the value of farm land and buildings owned is given for each state in the 1950 Census of Agriculture [19, Vol. 1, Table 18]. But this set of data is not available in the 1959 census—the value of land and buildings is classified by size of farm (acres of land) but not by value. The procedure used to estimate the variance of land and buildings in 1959 was simply to add the change from 1950 to

One difficulty with the use of these data is that the definition of a rural farm family is not exactly the same as that of a farm in the Census of Agriculture. In addition, the capital data are incomplete; there is nothing on the distribution of non-agricultural assets owned by farmers. Also lacking is information about debt, which is needed to convert the size distribution of capital ownership for each state into a size distribution of net worth. At the national level, however, there was sufficient information to adjust for debt [19, Vol. 5, Pt. 4, Table 14]. This adjustment made only a small difference in the estimated inequality of capital ownership, reducing the estimated log variance of capital ownership from 1.88 to 1.86.[7]

Before these capital data can be aggregated with the labor income data, it is necessary to transform the variance of capital into the variance of income from capital. In the logarithmic form of equation (2), this transformation is made by multiplying the log variance of capital ownership by the square of the relative share of capital in total income. The method used to get estimates of the share of capital is summarized by the formula,

$$f_k = \left(\frac{rK}{rK + wL} \right) \alpha + C(1 - \alpha), \tag{4}$$

where α is the fraction of income of rural farm families from self-employment, C is the fraction of off-farm income that was not earnings, r is the rate of interest,[8] K is farm capital, w is the average farm wage rate, and L is average days worked per farm.

1959 in the variance of value classified by farm size to the variance of the 1950 value distribution. A similar method was used for machinery and the covariances between machinery and land. This procedure does not require that the variance of the proxy be the same as the variance of the true variable, but only that the relationship between them be the same in the two years.

[7] Because of the incompleteness of the capital data, it is encouraging that an independent estimate of $V(K)$ at the national level is quite close to the present estimates. Data of a Federal Reserve survey [15] yield an estimate of 1.77 as the log variance of net worth of "farm operators," with a mean value of $44,000 in 1962, of which $26,000 was farm business capital. My capital data give 1.86 as the log variance, and a mean value of $37,600 for net worth with $26,300 of agricultural assets in 1959. For the estimated share of capital in 1950, I obtained .312 and for 1959, .346. D. G. Johnson estimated a share of capital of .324 for 1950 [10, p. 165].

[8] The relevant rate of interest for estimating the variance of equilibrium income (r_e in equation (2)) will not be the average rate of return to agricultural capital so long as there is disequilibrium in the farm sector as a whole. An interest rate which seems more likely to reflect equilibrium conditions is that on the supply side. Accordingly, I used the rate on farm mortgage debt as a basis for r. Similarly, although in some ways using the wage rate paid to hired workers is an inferior measure of w_e, it does have an advantage under conditions of disequilibrium if the short-run elasticity of supply of hired farm labor is greater than that of self-employed labor.

The variance of equilibrium income

Estimates for each state of the elements of the logarithmic version of (2) are now complete. Aggregating these elements according to (2) yields the estimates of the standard deviation of the log of equilibrium income (VY_E) shown in Table 1. For purposes of comparison, the standard deviations of the logs of the Census of Population size distributions of income for rural farm families and unrelated individuals (VY) are also shown.

There is one striking difference between the measure of census income inequality and estimated long-run inequality; the inequality of the distribution of census income declined in practically every state from 1949 to 1959, but the inequality of equilibrium income shows no such decline and, in fact, generally increased. Are these differences merely a matter of the construction of the estimates? What can be said definitely is that the changes in the distributions of age, schooling, earners, race, and ownership of agricultural assets, and the changes in factor shares have been such as to cause the estimated increases in VY_E. It is possible that these factors have been offset by variables whose changes between 1949 and 1959 could not be measured—the coefficients of the income generating function, the covariance between labor and capital, or the non-agricultural capital left out.[9] But, unless these factors changed drastically, the reduction indicated by the census size distributions and by the data of Boyne [4] must be attributable predominately to short-run sources of income inequality or to the omission of capital gains.

Problems of measurement aside, the estimates of VY_E have several important advantages over the use of census income data. First, they yield indexes of income inequality free of the transitory component of income. For purposes of analyzing either the distribution of factor rewards or the inequality of economic welfare it is more meaningful not to include this component. Secondly, the variance of capital gains is explicitly included by using the distribution of capital ownership. Finally, non-money income is included since the valuation of assets takes into account all the returns expected from the ownership of them.

The mean value of estimated equilibrium income is $6400, compared with $4200 from the census data. The exclusion of capital gains and nonmoney income and the inclusion of (negative) disequilibrium returns in the census data each probably accounts for some of the measured difference. Since inequality is measured by log variances, the fact that the

---

[9] An additional problem in comparing 1949 and 1959 for both VY and VY_E is that the definition of a farm was changed in 1959. The data presented in Boyne [4, p. 1219], however, show little, if any, effect of the redefinition on measured income inequality.

Table 1. The standard deviations of the logs of total income (VY) and the standard deviations of the logs of equilibrium income (VY_E)[a]

---

[a] The standard deviation of the logs of census income is predicted from the concentration ratio by the method described in Aitchison and Brown [2, p. 112]. These size distributions are for rural farm families and unrelated individuals from [20, 1960, Table 65, and 1950, Table 32].

mean of the distribution is larger does not imply greater variance. Doubling the whole distribution leaves the log variance unchanged.

Long- and short-run inequality

Unless there is strong negative covariance between short- and long-run components of income, the presence of short-run inequality will make the variance of census income greater than the variance of equilibrium income. The more important the short-run components of income, the greater this difference will be. It would be a mistake, however, to consider the difference between VY and VY_E as a measure of short-run inequality in any absolute sense. The variance of census income is substantially underestimated just because of the grouping of income classes.[10] Given the measurement problems discussed above, it would likewise be unwise to regard VY_E as an absolute magnitude. Rather, both are only *relative* indexes, with which one can compare indexes constructed in the same way for other states and years.

Explaining State Differences in Inequality

None of the various hypotheses about the ultimate determinants of income inequality mentioned at the beginning of this paper deals explicitly with the kind of events that have been important in the recent history of U.S. agriculture. Of main interest are the migration of labor from farming, increases in the quantity and quality of capital per farm, increased investment in skills, and government farm programs. This section is concerned with the reasons afforded by economic theory for expecting a connection between these events and income inequality and with the use of the data developed above to investigate these theoretical implications empirically.

The long run

Definite predictions can be made about relative factor shares. Given that income from capital is more unequally distributed than labor income, anything that increases the relative share of capital should increase income inequality.[11]

---

[10] Welch found that when he expanded the size distribution of farm operator income from classes of \$1000 to classes of \$10, the log variance went from .92 to 1.82 [22, p. 13].

[11] That capital income variance is greater than labor income variance is not, however, a sufficient condition for an increase in capital share to lead to increased income inequality. From equation (3) we have

$$C^2(Y) = f_k^2C^2(K) + (1 - f_k)^2C^2(L) + 2f_k(1 - f_k)\rho C_LC_K.$$

The effect of a change in capital's share, f_k, is

$$\frac{\partial C^2(Y)}{\partial f_k} = 2f_kC^2(K) - 2(1 - f_k)C^2(L) + 2(1 - 2f_k)\rho C_LC_K.$$

Increases in the quantity of capital per farm and decreases in the farm labor force both can be expected to increase the share of capital so long as the elasticity of substitution between labor and capital is greater than unity. On the other hand, Schultz [17] has hypothesized that investment in human capital may have increased the share of labor. With respect to technical change, the question whether it will be biased or neutral with respect to factor shares cannot be answered a priori.

The preceding comments make use of the distinction between labor and capital. Further propositions can be inferred by treating land separately from other forms of non-human wealth. The view of Marx, for example, that increases in average wealth are "identical with the increase of poverty" [12, p. 97] seems to be based partially on the expectation of an ever larger share of income going to the relatively fixed and unequally distributed factor, land. Such a process ought to be especially noticeable in the agricultural sector. A similar inference can be made with respect to the consequences of government programs. To the extent that they increase the income share of land, owing to its relatively low elasticity of supply, they will increase income inequality.

These events will also alter income inequality if they change the variance or covariance of factor ownership. The consequences of increased schooling or government payments depend upon the position in the income distribution of the recipients. Likewise, to the extent that off-farm migrants are selected from the lower part of the income distribution, migration will reduce income inequality among those who remain. But it is not at all clear that migrants have been, or can be expected to be, drawn from the poorer farmers. In general, the a priori expectations about any of these selectivity effects are weak.

Short-run effects

With respect to technical progress, consider the impact of a new development that concerns only a subset of farmers, e.g., a more efficient machine for harvesting some crop. Such an invention will change income inequality according to the position in the income distribution of those who can benefit from it. In addition, there is the fact that when any improvement occurs, those who are first to adopt it successfully gain, and those who are slow to adjust lose.

Migration and the taking of off-farm work by farm residents and their families can also be expected to have short-run consequences. In general,

---

This expression may be either positive or negative. As typical values for these variables for the United States, we get $1.1-.8+.2=.5$ for the value of the partial; this implies that an increase in f_k of the order of magnitude that we had from 1950 to 1960, about .03, would increase the log variance of income by about .015, or approximately a one percent increase in income inequality.

the main short-run impact of such labor market adjustments should be to reduce inequality due to disequilibrium, since such inequality is due to immobility and these adjustments are precisely the overcoming of immobility.

Regression Analysis

The preceding paragraphs have suggested reasons why some recent events in U.S. agriculture should have influenced income inequality. The object of the present section is to discover to what extent differences in income inequality between states and over time are, in fact, explainable in terms of these factors. Following the discussion above, long-run and short-run aspects of inequality are treated separately.[12] The method used is state cross-sectional regressions that have as dependent variables estimated income inequality for 1949 and 1959, as given in Table 1. The independent variables are intended to represent important aspects of recent changes in U.S. agriculture.

Following is the rationale for this approach: The goal of the analysis is to assess the influence of certain causal factors on income inequality, using observations of state size distributions of income. What makes this not a simple task is that many factors are varying at once, so that one cannot look at state differences and tell what particular factors are causing the differences. In this context, regression can be considered simply as an attempt to hold all other relevant variables constant. Now, for some causal factors, this may not be the best way to analyze the problem. To investigate the consequences of the introduction of a new machine, for example, it would be better to look at adopting farmers vis-a-vis others for the whole United States, rather than to put variables about the machine into state cross-sectional regressions. However, for variables of a general nature (e.g., migration), whose effects are not concentrated on any particular subset of the population but which have general consequences arising from factor share changes, etc., the regression approach provides a good method of getting at their net consequences.

Elements of mutual determination

Short-run and long-run inequality have been discussed as independent, separable variables. This independence, however, does not hold if short-run differences in rates of return persist over time. Under such conditions, short-run inequality will affect long-run inequality, owing to the accumulation of wealth from the part of these returns that is saved.

---

[12] The short-run component is measured as the residual between the estimated variance of equilibrium income and the variance of total income. This residual is a conglomeration of transitory income, the short-run variance in income due to disequilibrium, and the covariances of these components with equilibrium income, as well as the variance of capital gains and income in kind. The resulting random and systematic error is reflected in the generally lower R^2 and higher standard errors for the short-run regressions.

There are also identification problems due to the mutual determination of income inequality and some of the variables influencing it. Notably, migration has been treated as an equilibrating mechanism, but it is also an indicator of disequilibrium. Similarly, off-farm work by farm family members should reduce short-run inequality, but it is by the same token likely to be taken in response to short-run fluctuations in income. The first effect yields a negative correlation between off-farm work and inequality, and the second a positive one.

In the regressions that follow, I dealt with this problem by the use of lagged variables, using for migration, net migration for the five years *preceding* the year for which income inequality is observed. I also computed regressions for changes from 1949 to 1959 in income inequality. This procedure leaves aside the cumulative effects of past interaction on the levels of inequality that we observe at any given time and enables us to relate changes in inequality directly to contemporaneous changes in the independent variables. The regressions are presented in Table 2.

Interpretation of the regression results

Consider first the variables relating to labor market adjustment. "Migration" here measures the mobility of labor out of the farming occupation, rather than residential movement. Since the capital/labor variable (X_5) should pick up the factor share effects of migration, the sign of the migration variable itself (X_1) probably reflects primarily the selectivity of migration. The high standard error and varying sign of this variable do not indicate that the selection of migrants has been anything other than random. Occupational mobility does, however, appear to have been influential in reducing short-run inequality, as was expected.

It was expected that off-farm work would be associated with decreases in short-run inequality, but the significance of this variable (X_2) in reducing long-run income inequality was somewhat surprising. It may be that the kind of process observed by Tang in the Piedmont is at work [18, pp. 160–62]—that under conditions of capital rationing, off-farm work enables poor farmers to add to their own capital stock, thus decreasing the inequality of wealth and of equilibrium income.

In relation to off-farm work, the degree of income inequality in the non-farm sector becomes important, in particular as related to the relative wages of different skill groups. If high quality labor is scarce in the non-farm economy and its relative price rises in consequence, highly skilled labor in agriculture will be relatively more attracted to non-farm employment. Such adjustments will increase the income of farm people with the most human capital, thereby increasing income inequality within the farm

Table 2. Regression results: Long-run income inequality is the dependent variable, Y_1, short-run inequality is Y_2, and total inequality is Y_3

Independent variable	Dependent variable						
	Y_1	Y_1	Y_1	Y_1	Y_2	Y_2	Y_3

[a] Figures in parentheses are standard errors.

Sources: Y_1, long-run income inequality, and Y_3, census income inequality, are taken from Table 1. Y_2 is the square root of the difference between the log variance of census income and the log variance of equilibrium income.

"Migration" (X_1) is the total disappearance of farm labor during 1945–49 for the 1950 regressions and during 1954–59 for the 1960 regressions. Total disappearance was measured as the ratio of the number of farms times days of labor per farm for the earlier year divided by the same product for the later year. The data on days worked per farm is from Gisser [8, Table 30]. Data on off-farm work of farm operators was available on the punched cards used in Griliches [9]. Variables X_5 and X_8 also came from this source.

The ratio of high-skill wage rates to low-skill wage rates (X_3) was measured as the ratio of the median annual earnings of "craftsmen" over the median annual earnings of "laborers, except farm and mine," from [20, Vol. 1, Pt. 1, Table 140 (1960)].

X_4, X_6, X_7, X_{10}, and X_{12} were based on the distributions given in [20, Vol. 1, Pts. 2–52, Tables 32, 138, 139, 142 (1960); Vol II, Pts. 2–49, Table 20; Vol. IV, Pt. 2A, Table 30, 31, 34 (1950)].

X_9 is the log of government payments per farm as reported in [21, Table 4].

sector. This process is reflected in the strength of the variable representing the variance of wages by skill class (X_3) in the regressions on long-run inequality. Although this effect is caught by the schooling coefficients, and hence is measured as long-run inequality, strictly speaking, it is short-run inequality because it should in the long run be erased by investments in skills until the rate of return on them falls to the normal rate. Whether this adjustment can occur, however, depends crucially on the ability of poor people to invest in skills. And, in fact, increases in the average level of schooling (X_6) are significantly associated with *increasing* long-run inequality.

The variance of earners per family and the age composition reflect differences in family structure of the kind analyzed by T. P. Schultz [16, p. 40]. These variables are used in the regressions to hold inequality constant with respect to state differences in the organization of families, the better to observe the economic impact of the other variables. From these regressions, it appears that the family structure, especially with respect to secondary earners, is quite important in determining observed differences between states and over time.

Next, we have a set of variables relating to the conditions of production in agriculture. The ratio of capital to labor (X_5) has the expected positive sign but is never significant. This result is consistent with other evidence that the elasticity of substitution between labor and other inputs is probably close to unity [9].

On the other hand, the research and extension coefficient (X_8) is significantly positive in all of the long-run regressions. Such activities appear either to have increased the share of capital or to have been so biased that higher income farmers were more readily able to take advantage of them.

The government payments variable (X_9) generally has the expected positive sign in the regressions on long-run inequality. The standard error is so large, however, that the null hypothesis that such programs have had no effect cannot be rejected at any level of significance. This may reflect the fact that, especially in 1949, government payments were a quite small part of farm income.

Finally, the mean level of income was included in order to identify any "residual" association between income level and income inequality. Aigner and Heins [1], following Kuznets [11], treated economic growth itself as a source of declining inequality. While average income was highly significant in the regression on total income inequality (Y_3), it was not significant and its sign varied in the regressions on long-run inequality. This result is consistent with Kuznets' own speculation that the observed association of growth with declining inequality may have been largely attributable to transitory income. It also adds to the suspicion that the decline in farm income inequality observed by Boyne [4] is attributable to short-run factors.

Concluding Remarks

For the regression analysis in general, the variables usually have the expected signs, and the explanatory power of the equations is quite good, especially considering the many deficiencies of specification and data availability. The main measurement problem was that of obtaining a meaningful index of income inequality with which to compare states. The results on the whole, if they do not demonstrate beyond doubt, at least are consistent with the general picture of the generation of income inequality that has been developed in this paper—particularly the proposition that disequilibrium and labor market adjustments have been important in the determination of the inequality of the distribution of personal income. The results also support the general view that state differences in U.S. farm income inequality are explainable on the basis of economic variables and have been not randomly determined, not constant, and not primarily a political matter.

From the point of view of public policy concerning income inequality, the most significant aspect of this investigation may be the result that the factors normally associated with "progress"—technical change, increases in schooling, and increased capital per farm—appear to have increased rather than decreased the variance of equilibrium income. This fact, together with the observation that the recent decline in total farm income inequality (as measured from census size distributions) apparently reflects mainly short-run components of income, does not encourage a sanguine view of the future prospects for automatically declining inequality. Before more definite and specific conclusions can be drawn in this area, however, research of a more detailed nature is required.

Econometric Analysis of the Agricultural Labor Market*

Edward W. Tyrchniewicz and G. Edward Schuh

Previous research on the market for agricultural labor is extended through the use of a simultaneous-equations model consisting of six equations. The model treats the markets for unpaid family and operator labor, both of which have been slighted in previous work, and takes account of the interdependence among the three components of the agricultural labor force. The demand and supply elasticities were found to differ substantially among the components. Economic implications suggested by the statistical results are analyzed, and the structural models are used to evaluate a number of alternative policies that bear on labor use and labor returns.

THE objective of the research reported in this article was to increase our knowledge about the market for agricultural labor.[1] The research extends previous work and makes a modification in the analytical model that, to the best of our knowledge, has not been considered in previous studies of the agricultural labor market.[2]
